This standard was developed by a consensus standards development process which has been accredited by the American National Standards Institute (ANSI). Accreditation by ANSI, a voluntary accreditation body representing public and private sector standards development organizations in the United States and abroad, signifies that the standards development process used by ASCE has met the ANSI requirements for openness, balance, consensus, and due process.

While ASCE's process is designed to promote standards that reflect a fair and reasoned consensus among all interested participants, while preserving the public health, safety, and welfare that is paramount to its mission, it has not made an independent assessment of and does not warrant the accuracy, completeness, suitability, or utility of any information, apparatus, product, or process discussed herein. ASCE does not intend, nor should anyone interpret, ASCE's standards to replace the sound judgment of a competent professional, having knowledge and experience in the appropriate field(s) of practice, nor to substitute for the standard of care required of such professionals in interpreting and applying the contents of this standard.

ASCE has no authority to enforce compliance with its standards and does not undertake to certify products for compliance or to render any professional services to any person or entity.

ASCE disclaims any and all liability for any personal injury, property damage, financial loss, or other damages of any nature whatsoever, including without limitation any direct, indirect, special, exemplary, or consequential damages, resulting from any person's use of, or reliance on, this standard. Any individual who relies on this standard assumes full responsibility for such use.

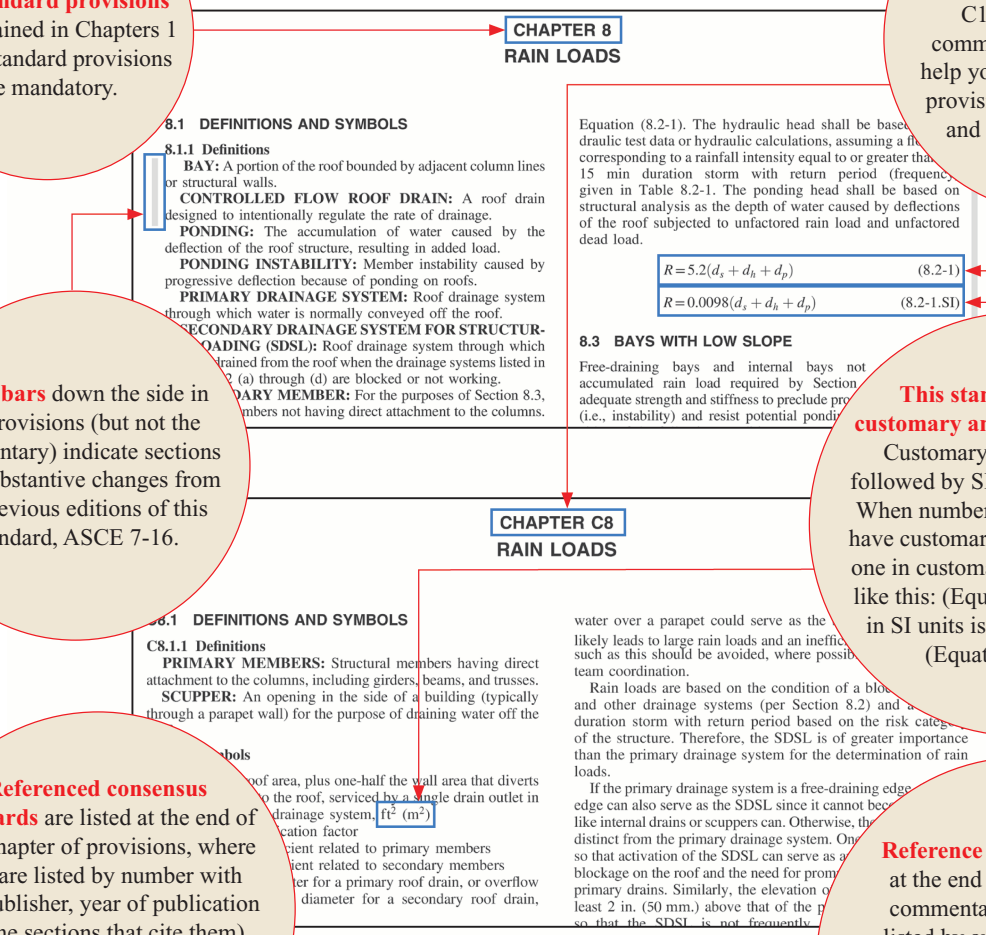
ASCE STANDARDS



In 2016, the Board of Direction approved revisions to the ASCE Rules for Standards Committees to govern the writing and maintenance of standards developed by ASCE. All such standards are developed by a consensus standards process managed by the ASCE Codes and Standards Committee. The consensus process includes balloting by a balanced standards committee and reviewing during a public comment period. All standards are updated or reaffirmed by the same process every five or six years. Requests for formal interpretations shall be processed in accordance with Section 7 of ASCE Rules for Standards Committees, which are available at www.asce.org. Errata, addenda, supplements, and interpretations, if any, for this standard can also be found at www.asce.org. This standard has been prepared in accordance with recognized engineering principles and should not be used without the user's competent knowledge for a given application. The publication of this standard by ASCE is not intended to warrant that the information contained therein is suitable for any general or specific use, and ASCE takes no position respecting the validity of patent rights. The user is advised that the determination of patent rights or risk of infringement is entirely their own responsibility. A complete list of currently available standards is available in the ASCE Library (https://ascelibrary.org/).

Tips for Using This Standard

The **standard provisions** are contained in Chapters 1 to 32. Standard provisions are mandatory.

The **standard commentary** is contained in Chapters C1 to C32. Standard commentary is intended to help you understand how the provisions were determined and how to apply them.

CHAPTER 8
RAIN LOADS

8.1 DEFINITIONS AND SYMBOLS

8.1.1 Definitions

BAY: A portion of the roof bounded by adjacent column lines or structural walls.

CONTROLLED FLOW ROOF DRAIN: A roof drain designed to intentionally regulate the rate of drainage.

PONDING: The accumulation of water caused by the deflection of the roof structure, resulting in added load.

PONDING INSTABILITY: Member instability caused by progressive deflection because of ponding on roofs.

PRIMARY DRAINAGE SYSTEM: Roof drainage system through which water is normally conveyed off the roof.

SECONDARY DRAINAGE SYSTEM FOR STRUCTURAL LOADING (SDSL): Roof drainage system through which water is drained from the roof when the drainage systems listed in ... (a) through (d) are blocked or not working.

...DARY MEMBER: For the purposes of Section 8.3, ...mbers not having direct attachment to the columns.

Equation (8.2-1). The hydraulic head shall be based ... draulic test data or hydraulic calculations, assuming a fl... corresponding to a rainfall intensity equal to or greater tha... 15 min duration storm with return period (frequenc... given in Table 8.2-1. The ponding head shall be based on structural analysis as the depth of water caused by deflections of the roof subjected to unfactored rain load and unfactored dead load.

$$R = 5.2(d_s + d_h + d_p) \quad (8.2\text{-}1)$$

$$R = 0.0098(d_s + d_h + d_p) \quad (8.2\text{-}1.SI)$$

8.3 BAYS WITH LOW SLOPE

Free-draining bays and internal bays not ... accumulated rain load required by Section ... adequate strength and stiffness to preclude pro... (i.e., instability) and resist potential pondi...

CHAPTER C8
RAIN LOADS

C8.1 DEFINITIONS AND SYMBOLS

C8.1.1 Definitions

PRIMARY MEMBERS: Structural members having direct attachment to the columns, including girders, beams, and trusses.

SCUPPER: An opening in the side of a building (typically through a parapet wall) for the purpose of draining water off the ...

...bols

...oof area, plus one-half the wall area that diverts ...o the roof, serviced by a single drain outlet in ... drainage system, ft² (m²)

...cation factor

...cient related to primary members

...ient related to secondary members

...ter for a primary roof drain, or overflow ... diameter for a secondary roof drain,

water over a parapet could serve as the ... likely leads to large rain loads and an ineffi... such as this should be avoided, where possib... team coordination.

Rain loads are based on the condition of a blo... and other drainage systems (per Section 8.2) and ... duration storm with return period based on the risk categ... of the structure. Therefore, the SDSL is of greater importance than the primary drainage system for the determination of rain loads.

If the primary drainage system is a free-draining edge ... edge can also serve as the SDSL since it cannot bec... like internal drains or scuppers can. Otherwise, th... distinct from the primary drainage system. On... so that activation of the SDSL can serve as a... blockage on the roof and the need for prom... primary drains. Similarly, the elevation o... least 2 in. (50 mm.) above that of the p... so that the SDSL is not frequently ...

Gray bars down the side in the provisions (but not the commentary) indicate sections with substantive changes from the previous editions of this standard, ASCE 7-16.

This standard uses both customary and metric (SI) units. Customary units appear first, followed by SI units in parentheses. When numbered display equations have customary and SI versions, the one in customary units is numbered like this: (Equation 8.2-1). The one in SI units is numbered like this: (Equation 8.2-1.SI).

Referenced consensus standards are listed at the end of each chapter of provisions, where they are listed by number with title, publisher, year of publication (and the sections that cite them). In text, they are mentioned only by number: *AASHTO LRFD Bridge Design Specifications*, ASME A17.1.

Reference citations are listed at the end of each chapter of commentary, where they are listed by author and date with accompanying bibliographic information. In the text, these references are called out by author and date: Baber and Rigsbee (2010); Bodhaine (1968); and Carter (1957).

4.17 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

This section lists the consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

AASHTO LRFD Bridge Design Specifications, 7th ed., American Association of State Highway and Transportation Officials, 2014, with 2015 interim revisions.

Tips for Using the ASCE 7 Hazard Tool

asce7hazardtool.online

The ASCE 7 Hazard Tool provides access to the digital data defined in the hazard Geodatabases required by this standard. The digital data required for snow, seismic, and tornado are available at https://asce7hazardtool.online/, and digital data is available for flood, rain, ice, and wind, as well. Digital data required for tsunami is available at https://asce7tsunami.online/.

Digital Data

The ASCE 7 Hazard Tool provides digital data required by ASCE 7-22:

- Ch. 5 Flood: Flood zone and static base flood elevation, plus direct links to additional information
- Ch. 6 Tsunami: Whether the site is in a mapped tsunami design zone per the ASCE Tsunami Design Geodatabase, and link to ASCE Tsunami Design Geodatabase if required for design
- Ch. 7 Snow: Ground snow load and winter wind parameter
- Ch. 8 Rain: Median 15-minute and 60-minute duration rainfall intensities for 100-year mean recurrence interval
- Ch. 10 Ice: Radial ice thickness with concurrent 3-second gust speeds and temperature concurrent with ice thickness due to freezing rain
- Ch. 22 Seismic: Seismic coefficients S_S, S_1, S_{MS}, S_{M1}, S_{DS}, S_{D1}, T_L, PGA_M, and V_{S30}, plus the seismic design category, as well as the multi-period spectrum, the multi-period MCE_R spectrum, the two-period design spectrum, and the two-period MCE_R spectrum
- Ch. 26 Wind: Three-second gust wind speeds at 33 feet (10 meters) above ground for Exposure Category C, including identification of hurricane-prone and wind-borne debris regions
- Ch. 32 Tornado: Tornado wind speeds for 1,700-, 3,000-, 10,000-, 100,000-, 1,000,000-, and 10,000,000-year MRI, and for 1-, 2,000-, 10,000-, 40,000-, 100,000-, 250,000-, 1,000,000-, and 4,000,000-ft_2. target areas

APPENDIX D BUILDINGS EXEMPTED FROM TORSIONAL WIND LOAD CASES . . . 403
D.1 Scope . . . 403
D.2 One- and Two-Story Buildings Meeting the Following Requirements . . . 403
D.3 Buildings Controlled by Seismic Loading . . . 403
D.3.1 Buildings with Diaphragms at Each Level That Are Not Flexible . . . 403
D.3.2 Buildings with Diaphragms at Each Level That Are Flexible . . . 403
D.4 Buildings Classified as Torsionally Regular Under Wind Load . . . 403
D.5 Buildings with Diaphragms that are Flexible and Designed for Increased Wind Loading . . . 403

APPENDIX E PERFORMANCE-BASED DESIGN PROCEDURES FOR FIRE EFFECTS ON STRUCTURES . . . 405
E.1 Scope . . . 405
E.2 Definitions . . . 405
E.3 General Requirements . . . 405
E.4 Performance Objectives . . . 405
E.4.1 Structural Integrity . . . 405
E.4.2 Project-Specific Performance Objectives . . . 406
E.5 Thermal Analysis of Fire Effects . . . 406
E.5.1 Fuel Load . . . 406
E.5.2 Structural Design Fires . . . 406
E.5.3 Heat Transfer Analysis . . . 406
E.6 Structural Analysis of Fire Effects . . . 406
E.6.1 Temperature History for Structural Members and Connections . . . 406
E.6.2 Temperature-Dependent Properties . . . 406
E.6.3 Load Combinations . . . 406

APPENDIX F WIND HAZARD MAPS FOR LONG RETURN PERIODS . . . 407
F.1 Scope . . . 407
F.2 Wind Speeds . . . 407

APPENDIX G TORNADO HAZARD MAPS FOR LONG RETURN PERIODS . . . 415
G.1 Scope . . . 415
G.2 Tornado Speeds . . . 415

COMMENTARY TO STANDARD ASCE/SEI 7-22

Commentary contents appear in second book

C1 GENERAL . . . 483
C1.1 Scope . . . 483
C1.3 Basic Requirements . . . 483
C1.3.1 Strength and Stiffness . . . 483
C1.3.1.3 Performance-Based Procedures . . . 484
C1.3.2 Serviceability . . . 488
C1.3.3 Functionality . . . 488
C1.3.4 Self-Straining Forces and Effects . . . 489
C1.3.7 Fire Resistance . . . 489
C1.4 General Structural Integrity . . . 489
C1.5 Classification of Buildings and Other Structures . . . 491
C1.5.1 Risk Categorization . . . 491
C1.5.3 Toxic, Highly Toxic, and Explosive Substances . . . 492
C1.6 In Situ Load Tests . . . 494
References . . . 494
Other References (not cited) . . . 495

C2 COMBINATIONS OF LOADS . . . 497
C2.1 General . . . 497
C2.2 Symbols . . . 497
C2.3 Load Combinations for Strength Design . . . 497
C2.3.1 Basic Combinations . . . 497
C2.3.2 Load Combinations Including Flood Load . . . 498
C2.3.3 Load Combinations Including Atmospheric Ice and Wind-on-Ice Loads . . . 499
C2.3.4 Load Combinations Including Self-Straining Forces and Effects . . . 500
C2.3.5 Load Combinations for Nonspecified Loads . . . 500
C2.3.6 Basic Combinations with Seismic Load Effects . . . 501
C2.3.7 Alternative Method for Loads from Water in Soil . . . 501
C2.4 Load Combinations for Allowable Stress Design . . . 501
C2.4.1 Basic Combinations . . . 501
C2.4.2 Load Combinations Including Flood Load . . . 502
C2.4.3 Load Combinations Including Atmospheric Ice and Wind-on-Ice Loads . . . 502
C2.4.4 Load Combinations Including Self-Straining Forces and Effects . . . 502
C2.4.5 Basic Combinations with Seismic Load Effects . . . 503
C2.5 Load Combinations for Extraordinary Events . . . 503
References . . . 504
Other References (not cited) . . . 505

C3 DEAD LOADS, SOIL LOADS, AND HYDROSTATIC PRESSURE . . . 507
C3.1 Dead Loads . . . 507
C3.1.2 Weights of Materials of Construction . . . 507
C3.1.3 Weight of Fixed Service Equipment . . . 507
C3.1.4 Vegetative and Landscaped Roofs . . . 507
C3.1.5 Solar Panels . . . 507
C3.2 Soil Loads and Hydrostatic Pressure . . . 507
C3.2.1 Lateral Pressures . . . 507
C3.2.2 Uplift Loads on Floors and Foundations . . . 514
C3.3 Alternative Method for Loads from Water in Soil . . . 514

PREFACE

Prepared by the Minimum Design Loads and Associated Criteria for Buildings and Other Structures Standards Committee of the Codes and Standards Activity Division of the Structural Engineering Institute of ASCE

ASCE/SEI 7-22 Minimum Design Loads and Associated Criteria for Buildings and Other Structures provides the most up-to-date and coordinated loading provisions for general structural design. ASCE 7-22 prescribes design loads for all hazards including dead, live, soil, flood, tsunami, snow, rain, atmospheric ice, seismic, wind, and fire, as well as how to evaluate load combinations. The 2022 edition of ASCE 7, which supersedes ASCE 7-16, coordinates with the most current structural material standards including those from ACI, AISC, AISI, AWC, and TMS.

Significant technical changes include the following:

- General Requirements
  - New target reliability tables for tsunami and extraordinary loads
  - Removal of importance factors for snow and ice due to risk category specific maps being provided
  - Expanded provisions for in situ load testing
- Load Combinations
  - Revised load combinations to reflect changes in snow loads and new tornado loads
  - New alternative method for loads from water in soil
  - Load combinations for flood loads and atmospheric ice are now explicitly written out and numbered for improved reference and clarity
- Dead and Live Loads
  - Reformatted lateral soil loads table for improved clarity
  - New alternative method for loads from water in soil
  - Terminology change from guardrail system to guard system
  - Additions and clarifications to the live load table
  - Updated crane load vertical impact force provisions including the use of bridge crane service classes
  - New provisions for emergency vehicle loads
- Tsunami Loads and Effects
  - Clarification for inundation calculations for overwashed areas
  - Updated data for Hawaii and many populous locations in California, coordinated with the state agencies
  - New provisions for above-ground horizontal pipelines
  - Clarifications and new provisions for debris impact analysis
  - New provisions for loss of foundation strength and scour
- Snow Loads
  - Ground snow loads have been revised to reflect more recent snow load data and reliability-targeted values
  - Method for estimating drifts revised to include a wind parameter
  - A more accurate estimation of the horizontal extent of windward drifts
  - Revised thermal factors to account current trends in roof insulation and venting
- Rain Loads
  - Design rain load revised to explicitly consider a ponding head
  - New commentary for low slope roofs and drainage to existing roofs
- Atmospheric Ice Loads
  - New risk-targeted atmospheric ice load data for the continental United States and Alaska
- Seismic Design
  - Multi-period response spectrum data eliminates need for F_a and F_v coefficients
  - Increase in number of site class definitions
  - Updated provisions for two-stage analysis procedures
  - Updated provisions for calculating torsion impacts, including irregularities (new Torsional Irregularity Ratio (TIR) term] and accidental torsion
  - Updated directional loading provisions
  - Updated analysis procedure selection provisions
  - Updated displacement and drift provisions
  - Updated force equations for nonstructural components
  - New provisions for penthouses and equipment and distribution system support structures
  - New Lateral Force Resisting Systems:
    - Steel and Concrete Coupled Composite Plate Shear Walls
    - Reinforced Concrete Ductile Coupled Shear Walls
    - Cross-laminated Timber Shear Walls
    - Concrete Tabletop Structures
  - New provisions for Rigid Wall, Flexible Diaphragm buildings (big box stores/warehouses)
  - New and updated provisions for supported and interconnected (coupled) nonbuilding structures
- Wind Design
  - Updates to the wind speed maps along hurricane coastline
  - Removal of tabular methods for both the directional and the envelope procedures, and C&C
  - New provisions for MWFRS and C&C of elevated buildings
  - Updated and expanded provisions for roof and ground-mounted solar
  - Updated provisions grouped circular bins and tanks
  - Revisions to the (GC_p) graphs for external pressure coefficients on C&C
  - Updates for wind tunnel testing and adoption of new edition of ASCE 49-22
  - New chapter for tornado provisions
  - New long return period hazard maps for wind and tornado
- Digital Data Available for all Hazards
  - Required to use digital data for tsunami, snow, seismic
  - Provided for flood, rain, ice, wind, tornado

In addition to the technical changes, the 2022 edition of the ASCE 7 provisions are accompanied by a detailed commentary with explanatory and supplementary information developed to assist users of the standard, including design practitioners, building code committees, and regulatory authorities.

ASCE 7 is an integral part of building codes in the United States and around the globe and is adopted by reference into the International Building Code, International Existing Building Code, International Residential Code, and NFPA 5000 Building Construction and Safety Code. Structural engineers, architects, and those engaged in preparing and administering local building codes will find the structural load requirements essential to their practice.

@seismicisolation

ACKNOWLEDGMENTS

The American Society of Civil Engineers (ASCE) acknowledges the work of the Minimum Design Loads and Associated Criteria for Buildings and Other Structures Standards Committee of the Codes and Standards Activities Division of the Structural Engineering Institute. This group comprises individuals from many backgrounds, including consulting engineering, research, construction industry, education, government, design, and private practice.

This revision of the standard began in 2017 and incorporates information as described in the preface. This standard was prepared through the consensus standards process by balloting in compliance with procedures of ASCE's Codes and Standards Activities Committee. The individuals who serve on the Standards Committee are listed as follows.

ASCE 7-22 Minimum Design Loads and Associated Criteria for Buildings and Other Structures Standards Committees

DEDICATION

Jon A. Peterka, Ph.D., P.E.

May 26, 1941 – May 22, 2019

ASCE 7-22 is dedicated to Dr. Jon A Peterka, P.E., a leader in the development of codes and standards for ASCE who served on the ASCE/SEI 7 Minimum Design Loads and Associated Criteria for Buildings and Other Structures committee for several decades and was relied on for thoughtful guidance as the ASCE 7 wind load provisions evolved. Jon was a pioneer and community pillar of wind engineering. He was instrumental in the writing of the first version of ASCE 49 *Wind Tunnel Testing for Buildings and Other Structures* (and its antecedent, ASCE Manual of Practice 67). This service to our profession was only the tip of the iceberg in his passion for his work. Jon's imprint can be found throughout this standard, certainly in the knowledge and methods he contributed but also in the spirit in which we strive to provide the information necessary to improve the transparency, consistency, and quality of wind load provisions and wind tunnel testing.

@seismicisolation

CHAPTER 1
GENERAL

1.1 SCOPE

This standard provides minimum loads, hazard levels, associated criteria, and intended performance goals for buildings, other structures, and their nonstructural components that are subject to building code requirements. The loads, load combinations, and associated criteria provided herein are to be used with design strengths or allowable stress limits contained in design specifications for conventional structural materials. Used together, they are deemed capable of providing the intended performance levels for which the provisions of this standard have been developed. Procedures for applying alternative means to demonstrate acceptable performance are also described. Unless explicitly noted in this standard, specific criteria for additions, alterations, or repairs to existing buildings are beyond the scope of this standard.

1.2 DEFINITIONS AND SYMBOLS

1.2.1 Definitions The following definitions apply to all the provisions of the standard.

ALLOWABLE STRESS DESIGN: A method of proportioning structural members such that elastically computed stresses produced in the members by nominal loads do not exceed specified allowable stresses (also called "working stress design").

AUTHORITY HAVING JURISDICTION: The organization, political subdivision, office, or individual charged with the responsibility of administering and enforcing the provisions of this standard.

BUILDINGS: Structures, usually enclosed by walls and a roof, constructed to provide support or shelter for an intended occupancy.

DESIGN STRENGTH: The product of the nominal strength and a resistance factor.

DESIGNATED NONSTRUCTURAL SYSTEM: A nonstructural component or system that is essential to the intended function of a Risk Category IV structure or that is essential to Life Safety in structures assigned to other Risk Categories.

ESSENTIAL FACILITIES: Buildings and other structures that are intended to remain operational in the event of extreme environmental loading from flood, wind, tornado, snow, or earthquakes.

FACTORED LOAD: The product of the nominal load and a load factor.

HIGHLY TOXIC SUBSTANCE: As defined in 29 CFR 1910.1200, Appendix A, with Amendments as of February 1, 2000.

IMPORTANCE FACTOR: A factor that accounts for the degree of risk to human life, health, and welfare associated with damage to property or loss of use or functionality.

LIMIT STATE: A condition beyond which a structure or member becomes unfit for service and is judged either to be no longer useful for its intended function (serviceability limit state) or to be unsafe (strength limit state).

LOAD EFFECTS: Forces and deformations produced in structural members by the applied loads.

LOAD FACTOR: A factor that accounts for deviations of the actual load from the nominal load, for uncertainties in the analysis that transform the load into a load effect, and for the probability that more than one extreme load will occur simultaneously.

LOADS: Forces or other actions that result from the weight of all building materials, occupants and their possessions, environmental effects, differential movement, and restrained dimensional changes. Permanent loads are loads in which variations over time are rare or of small magnitude. All other loads are variable loads (see also *nominal loads*).

NOMINAL LOADS: The magnitudes of the loads specified in this standard for dead, live, soil, wind, tornado, snow, rain, flood, and earthquake loads.

NOMINAL STRENGTH: The capacity of a structure or member to resist the effects of loads as determined by computations using specified material strengths and dimensions and formulas derived from accepted principles of structural mechanics or by field tests or laboratory tests of scaled models, allowing for modeling effects and differences between laboratory and field conditions.

OCCUPANCY: The purpose for which a building or other structure, or part thereof, is used or intended to be used.

OTHER STRUCTURES: Structures other than buildings for which loads are specified in this standard.

P-DELTA EFFECT: The second-order effect on shears and moments of frame members induced by axial loads on a laterally displaced building frame.

PERFORMANCE-BASED PROCEDURES: An alternative to the prescriptive procedures in this standard characterized by project-specific engineering analysis, optionally supplemented by limited testing, to determine the computed reliability of an individual building or structure.

RESISTANCE FACTOR: A factor that accounts for deviations of the actual strength from the nominal strength and the manner and consequences of failure (also called "strength reduction factor").

RISK CATEGORY: A categorization of buildings and other structures for determination of flood, wind, tornado, snow, ice, and earthquake loads based on the risk associated with unacceptable performance. See Table 1.5-1.

SERVICE LOADS: Loads imparted on a building or other structure because of (1) self-weight and superimposed dead load, (2) live loads assumed to be present during normal occupancy or

@seismicisolation
@seismicisolation

use of the building or other structure, (3) environmental loads that are expected to occur during the defined service life of a building or other structure, and (4) self-straining forces and effects. Service live loads and environmental loads for a particular limit state are permitted to be less than the design loads specified in the standard. Service loads shall be identified for each serviceability state being investigated.

STRENGTH DESIGN: A method of proportioning structural members such that the computed forces produced in the members by the factored loads do not exceed the member design strength (also called "load and resistance factor design").

TOXIC SUBSTANCE: As defined in 29 CFR 1910.1200, Appendix A, with Amendments as of February 1, 2000.

1.2.2 Symbols The following symbols apply only to the provisions of Chapter 1 as indicated:

D = Dead load
F_x = Minimum design lateral force applied to level x of the structure and used for purposes of evaluating structural integrity in accordance with Section 1.4.2
L = Live load
L_r = Roof live load
N = Notional load for structural integrity
R = Rain load
S = Snow load
W_x = Portion of the total dead load of the structure, D, located or assigned to level x

1.3 BASIC REQUIREMENTS

1.3.1 Strength and Stiffness Buildings and other structures, and all parts thereof, shall be designed and constructed with adequate strength and stiffness to provide structural stability, protect nonstructural components and systems, and meet the serviceability requirements of Section 1.3.2.

Acceptable strength shall be demonstrated using one or more of the following procedures:

(a) The strength procedures of Section 1.3.1.1;
(b) The allowable stress procedures of Section 1.3.1.2; or
(c) Subject to the approval of the Authority Having Jurisdiction for individual projects, the performance-based procedures of Section 1.3.1.3.

It shall be permitted to use alternative procedures for different parts of a structure and for different load combinations subject to the limitations of Chapter 2. Where resistance to extraordinary events is considered, the procedures of Section 2.5 shall be used.

1.3.1.1 Strength Procedures Structural and nonstructural components and their connections shall have adequate strength to resist the applicable load combinations of Section 2.3 of this standard without exceeding the applicable strength limit states for the materials of construction.

1.3.1.2 Allowable Stress Procedures Structural and nonstructural components and their connections shall have adequate strength to resist the applicable load combinations of Section 2.4 of this standard without exceeding the applicable allowable stresses for the materials of construction.

1.3.1.3 Performance-Based Procedures Structural and nonstructural components and their connections designed with performance-based procedures shall be demonstrated by analysis in accordance with Section 2.3.5 or by analysis procedures supplemented by testing to provide a reliability that is generally consistent with the target reliabilities stipulated in this section. Structural and nonstructural components subjected to dead, live, environmental, and other loads except earthquake, tsunami, flood, and loads from extraordinary events shall be based on the target reliabilities in Table 1.3-1. Structural systems subjected to earthquake shall be based on the target reliabilities in Tables 1.3-2 and 1.3-3. The design of structures subjected to tsunami loads shall be based on the target reliabilities in Table 1.3-4. Structures, components, and systems that are designed for extraordinary events using the requirements of Section 2.5 for scenarios approved by the Authority Having Jurisdiction shall be based on the target reliabilities in Table 1.3-5. The analysis procedures used shall account for uncertainties in loading and resistance.

Testing methods in Sections 1.3.1.3.2 shall only be applied to individual projects and shall not be applied to development of values of material resistance for general use in structural systems.

Structures and nonstructural components shall meet the serviceability and functionality requirements of Sections 1.3.2 and 1.3.3.

Performance-based design provisions for structures subjected to tsunamis shall conform to the requirements of Chapter 6.

1.3.1.3.1 Analysis Analysis shall use rational methods based on accepted principles of engineering mechanics and shall consider all significant sources of deformation and resistance. Assumptions of stiffness, strength, damping, and other properties of components and connections incorporated in the analysis shall be based on approved test data or referenced standards.

1.3.1.3.2 Project-Specific Performance Capability Testing Testing used to substantiate the project-specific performance capability of structural and nonstructural components and their connections under load shall accurately represent the materials, configuration, construction, loading intensity, and boundary conditions anticipated in the structure. Where an approved industry standard or practice that governs the testing of similar components exists, the test program and determination of design values from the test program shall be in accordance with those industry standards and practices. Where such standards or practices do not exist, specimens shall be constructed to a scale similar to that of the intended application unless it can be demonstrated that scale effects are not significant to the indicated performance. Evaluation of test results shall be made on the basis of the values obtained from not less than three tests, provided that the deviation of any value obtained from any single test does not vary from the average value for all tests by more than 15%. If such deviation from the average value for any test exceeds 15%, then additional tests shall be performed until the deviation of any test from the average value does not exceed 15% or a minimum of six tests have been performed. No test shall be eliminated unless a rationale for its exclusion is given. Test reports shall document the location, the time and date of the test, the characteristics of the tested specimen, the laboratory facilities, the test configuration, the applied loading and deformation under load, and the occurrence of any damage sustained by the specimen, together with the loading and deformation at which such damage occurred.

1.3.1.3.3 Documentation The procedures used to demonstrate compliance with this section and the results of analysis and testing shall be documented in one or more reports submitted to the Authority Having Jurisdiction and to an independent peer review.

1.3.1.3.4 Peer Review The procedures and results of analysis, testing, and calculation used to demonstrate compliance with the requirements of this section shall be subject to an independent peer review approved by the Authority Having Jurisdiction. The peer review shall comprise one or more persons having the necessary expertise and knowledge to evaluate compliance,

@seismicisolation

Table 1.3-1. Target Reliability (Annual Probability of Failure, P_F) and Associated Reliability Indices (β) for Load Conditions That Do Not Include Earthquake, Tsunami, or Extraordinary Events.

	Risk Category			
Basis	**I**	**II**	**III**	**IV**
Failure that is not sudden and does not lead to widespread progression of damage	$P_F = 1.25 \times 10^{-4}$ per year $\beta = 2.5$	$P_F = 3.0 \times 10^{-5}$ per year $\beta = 3.0$	$P_F = 1.25 \times 10^{-5}$ per year $\beta = 3.25$	$P_F = 5.0 \times 10^{-6}$ per year $\beta = 3.5$
Failure that is either sudden or leads to widespread progression of damage	$P_F = 3.0 \times 10^{-5}$ per year $\beta = 3.0$	$P_F = 5.0 \times 10^{-6}$ per year $\beta = 3.5$	$P_F = 2.0 \times 10^{-6}$ per year $\beta = 3.75$	$P_F = 7.0 \times 10^{-7}$ per year $\beta = 4.0$
Failure that is sudden and results in widespread progression of damage	$P_F = 5.0 \times 10^{-6}$ per year $\beta = 3.5$	$P_F = 7.0 \times 10^{-7}$ per year $\beta = 4.0$	$P_F = 2.5 \times 10^{-7}$ per year $\beta = 4.25$	$P_F = 1.0 \times 10^{-7}$ per year $\beta = 4.5$

Notes:
[1]The target reliability indexes are provided for a 50-year reference period, and the probabilities of failure have been annualized. The equations presented in Section 2.3.6 are based on reliability indexes for 50 years, because the load combination requirements in Section 2.3.2 are based on the maximum loads for the 50-year reference period.
[2]Commentary to Section 2.5 includes references to publications that describe the historic development of these target reliabilities for earthquake, tsunami, or extraordinary events.

including knowledge of the expected performance, the structural and component behavior, the particular loads considered, structural analysis of the type performed, the materials of construction, and laboratory testing of elements and components to determine structural resistance and performance characteristics. The review shall include assumptions, criteria, procedures, calculations, analytical models, test setup, test data, final drawings, and reports. Upon satisfactory completion, the peer reviewers shall submit a letter to the Authority Having Jurisdiction indicating the scope of their review and their findings.

1.3.2 Serviceability Structural systems, and members thereof, shall be designed under service loads to have adequate stiffness to limit deflections, lateral drift, vibration, or any other deformations that adversely affects the intended use and performance of buildings and other structures based on requirements set forth in the applicable codes and standards or as specified in the project design criteria.

1.3.3 Functionality Structural systems and members and connections thereof assigned to Risk Category IV shall be designed with reasonable probability to have adequate structural strength and stiffness to limit deflections, lateral drift, or other deformations such that their behavior would not prevent function of the facility immediately following any of the design-level environmental hazard events specified in this standard. Designated nonstructural systems and their attachment to the structure shall be designed with sufficient strength and stiffness such that their behavior would not prevent function immediately following any of the design-level environmental hazard events specified in this standard. Components of designated nonstructural systems shall be designed, qualified, or otherwise protected such

@seismicisolation

that they shall be demonstrated capable of performing their critical function after the facility is subjected to any of the design-level environmental hazards specified in this standard.

The provisions in Sections 1.3.1.1 and 1.3.1.2 in this standard are deemed to comply with the requirements of this section.

1.3.4 Self-Straining Forces and Effects Provision shall be made for anticipated self-straining forces and effects arising from differential settlements of foundations and from restrained dimensional changes caused by temperature, moisture, shrinkage, creep, and similar effects.

1.3.5 Analysis Load effects on individual structural members shall be determined by methods of structural analysis that take into account equilibrium, general stability, geometric compatibility, and both short- and long-term material properties. Members that tend to accumulate residual deformations under repeated service loads shall have included in their analysis the added eccentricities expected to occur during their service life.

1.3.6 Counteracting Structural Actions All structural members and systems and all components and cladding in a building or other structure shall be designed to resist forces caused by earthquakes, wind, and tornadoes, with consideration of overturning, sliding, and uplift, and continuous load paths shall be provided for transmitting these forces to the foundation. Where sliding is used to isolate the elements, the effects of friction between sliding elements shall be included as a force. Where all or a portion of the resistance to these forces is provided by dead load, the dead load shall be taken as the minimum dead load likely to be in place during the event causing the considered forces. Consideration shall be given to the effects of vertical and horizontal deflections resulting from such forces.

1.3.7 Fire Resistance Structural fire resistance shall be provided in accordance with the requirements specified in the applicable building code. As an alternative, the performance-based design procedures in Appendix E are permitted, where approved.

1.4 GENERAL STRUCTURAL INTEGRITY

All structures shall be provided with a continuous load path in accordance with the requirements of Section 1.4.1 and shall have a complete lateral force-resisting system with adequate strength to resist the forces indicated in Section 1.4.2. All members of the structural system shall be connected to their supporting members in accordance with Section 1.4.3. Structural walls shall be anchored to diaphragms and supports in accordance with Section 1.4.4. The effects on the structure and its components caused by the forces stipulated in this section shall be taken as the notional load, N, and combined with the effects of other loads in accordance with the load combinations of Section 2.6. Where material resistance depends on load duration, notional loads are permitted to be taken as having a duration of 10 min. Structures designed in conformance with the requirements of this standard for Seismic Design Categories B, C, D, E, or F shall be deemed to comply with the requirements of Sections 1.4.2, 1.4.3, and 1.4.4.

1.4.1 Load Path Connections All parts of the structure between separation joints shall be interconnected to form a continuous path to the lateral force-resisting system, and the connections shall be capable of transmitting the lateral forces induced by the parts being connected. Any smaller portion of the structure shall be tied to the remainder of the structure with elements having the strength to resist a force of not less than 5% of the portion's weight.

1.4.2 Lateral Forces Each structure shall be analyzed for the effects of static lateral forces applied independently in each of two orthogonal directions. In each direction, the static lateral forces at all levels shall be applied simultaneously. For purposes of analysis, the force at each level shall be determined using Equation (1.4-1):

$$F_x = 0.01 W_x \tag{1.4-1}$$

where F_x is the design lateral force applied at story x, and W_x is the portion of the total dead load of the structure, D, located or assigned to level x.

Structures explicitly designed for stability, including second-order effects, shall be deemed to comply with the requirements of this section.

1.4.3 Connection to Supports A positive connection for resisting a horizontal force acting parallel to the member shall be provided for each beam, girder, or truss either directly to its supporting elements or to slabs designed to act as diaphragms. Where the connection is through a diaphragm, the member's supporting element shall also be connected to the diaphragm. The connection shall have the strength to resist a force of 5% of the unfactored dead load plus live load reaction imposed by the supported member on the supporting member.

1.4.4 Anchorage of Structural Walls Walls that provide vertical load bearing or lateral shear resistance for a portion of the structure shall be anchored to the roof and to all floors and members that provide lateral support for the wall or that are supported by the wall. The anchorage shall provide a direct connection between the walls and the roof or floor construction. The connections shall be capable of resisting a strength-level horizontal force perpendicular to the plane of the wall equal to 0.2 times the weight of the wall tributary to the connection, but not less than 5 lb/ft^2 (0.24 kN/m^2).

1.4.5 Extraordinary Loads and Events When considered, design for resistance to extraordinary loads and events shall be in accordance with the procedures of Section 2.5.

1.5 CLASSIFICATION OF BUILDINGS AND OTHER STRUCTURES

1.5.1 Risk Categorization Buildings and other structures shall be classified based on the risk to human life, health, and welfare associated with their damage or failure by nature of their occupancy or use, according to Table 1.5-1, for the purposes of applying flood, wind, tornado, snow, earthquake, and ice provisions. Each building or other structure shall be assigned to the highest applicable risk category or categories. Minimum design loads for structures shall incorporate the applicable Importance Factors given in Table 1.5-2, as required by other sections of this standard. Assignment of a building or other structure to multiple risk categories based on the type of load condition being evaluated (e.g., snow or seismic) shall be permitted.

When the building code or other referenced standard specifies an occupancy category, the risk category shall not be taken as lower than the occupancy category specified therein.

1.5.2 Multiple Risk Categories Where buildings or other structures are divided into portions with independent structural systems, the classification for each portion shall be permitted to be determined independently. Where building systems, such as required egress, HVAC, or electrical power, for a portion with a higher Risk Category pass through or depend on other portions of

@seismicisolation

Table 1.5-1. Risk Category of Buildings and Other Structures for Flood, Wind, Tornado, Snow, Earthquake, and Ice Loads.

Use or Occupancy of Buildings and Structures	Risk Category
Buildings and other structures that represent low risk to human life in the event of failure	I
All buildings and other structures except those listed in Risk Categories I, III, and IV	II
Buildings and other structures, the failure of which could pose a substantial risk to human life	III
Buildings and other structures not included in Risk Category IV, with potential to cause a substantial economic impact and/or mass disruption of day-to-day civilian life in the event of failure	
Buildings and other structures not included in Risk Category IV (including, but not limited to, facilities that manufacture, process, handle, store, use, or dispose of such substances as hazardous fuels, hazardous chemicals, hazardous waste, or explosives) containing toxic or explosive substances where the quantity of the material exceeds a threshold quantity established by the Authority Having Jurisdiction and is sufficient to pose a threat to the public if released*	
Buildings and other structures designated as Essential Facilities	IV
Buildings and other structures, the failure of which could pose a substantial hazard to the community	
Buildings and other structures (including, but not limited to, facilities that manufacture, process, handle, store, use, or dispose of such substances as hazardous fuels, hazardous chemicals, or hazardous waste) containing sufficient quantities of highly toxic substances where the quantity of the material exceeds a threshold quantity established by the Authority Having Jurisdiction and is sufficient to pose a threat to the public if released*	
Buildings and other structures required to maintain the functionality of other Risk Category IV structures	

*Buildings and other structures containing toxic, highly toxic, or explosive substances shall be eligible for classification to a lower risk category if it can be demonstrated to the satisfaction of the Authority Having Jurisdiction by a hazard assessment as described in Section 1.5.3 that a release of the substances is commensurate with the risk associated with that risk category.

the building or other structure having a lower risk category, those portions shall be assigned to the higher risk category.

1.5.3 Toxic, Highly Toxic, and Explosive Substances Buildings and other structures containing toxic, highly toxic, or explosive substances are permitted to be classified as Risk Category II structures if it can be demonstrated to the satisfaction of the Authority Having Jurisdiction by a hazard assessment as part of an overall risk management plan (RMP) that a release of the toxic, highly toxic, or explosive substances is not sufficient to pose a threat to the public.

To qualify for this reduced classification, the owner or operator of the buildings or other structures containing the toxic, highly toxic, or explosive substances shall have an RMP that incorporates three elements as a minimum: a hazard assessment, a prevention program, and an emergency response plan.

As a minimum, the hazard assessment shall include the preparation and reporting of worst-case release scenarios for each structure under consideration, showing the potential effect on the public for each. As a minimum, the worst-case event shall include the complete failure, for example, instantaneous release of the entire contents of a vessel, piping system, or other storage structure. A worst-case event includes, but is not limited to, a release during the design wind, design tornado, or design seismic event. In this assessment, the evaluation of the effectiveness of subsequent measures for accident mitigation shall be based on the assumption that the complete failure of the primary storage structure has occurred. The off-site impact shall be defined in terms of the population in the potentially affected area. To qualify for the reduced classification, the hazard assessment shall demonstrate that a release of the toxic, highly toxic, or explosive substances from a worst-case event does not pose a threat to the public outside the property boundary of the facility.

As a minimum, the prevention program shall consist of the comprehensive elements of process safety management, which is based on accident prevention through the application of management controls in the key areas of design, construction, operation, and maintenance. Secondary containment of the toxic, highly toxic, or explosive substances—including, but not limited to, double-wall tank, dike of sufficient size to contain a spill, or other means to contain a release of the toxic, highly toxic, or explosive substances within the property boundary of the facility and prevent release of harmful quantities of contaminants to the air, soil, groundwater, or surface water—is permitted to be used to mitigate the risk of release. Where secondary containment is provided, it shall be designed for all environmental loads and is not eligible for this reduced classification. In hurricane-prone regions, mandatory practices and procedures that effectively diminish the effects of wind on critical structural elements, or, alternatively, that protect against harmful releases during and after hurricanes, are permitted to be used to mitigate the risk of release.

As a minimum, the emergency response plan shall address public notification, emergency medical treatment for accidental exposure to humans, and procedures for emergency response to releases that have consequences beyond the property boundary of the facility. The emergency response plan shall address the potential that resources for response could be compromised by the event that has caused the emergency.

Table 1.5-2. Importance Factors by Risk Category of Buildings and Other Structures for Earthquake Loads.

Risk Category from Table 1.5-1	Seismic Importance Factor, I_e
I	1.00
II	1.00
III	1.25
IV	1.50

Notes: The component importance factor, I_p, applicable to earthquake loads is not included in this table because it depends on the importance of the individual component rather than that of the building as a whole, or its occupancy (see Section 13.1.3).

1.6 IN SITU LOAD TESTS

An in situ load test of any construction shall be conducted when required by the Authority Having Jurisdiction whenever there is

@seismicisolation

reason to question its safety for the intended use. In situ load tests shall be conducted in accordance with this section. The load test procedures of this section shall not be used to evaluate seismic load effects, tsunami loads, or loads from extraordinary events.

1.6.1 Load Test Procedure Specified Elsewhere Where the applicable building code or a material standard approved by the Authority Having Jurisdiction includes an applicable load test procedure and acceptance criteria, the load test shall be conducted in accordance with that code or standard.

1.6.2 Load Test Procedure Not Specified Elsewhere In the absence of an applicable load test procedure within the building code or an applicable material standard approved by the Authority Having Jurisdiction, a load test procedure shall be developed and overseen by a registered design professional, who will also be responsible for interpreting the results of the load test. At a minimum, the applied load shall be determined using the load factors specified in the basic combinations in Section 2.3.1. The applied load shall simulate applicable loading and deformation conditions relevant to the performance of the element or structure being tested. For statically loaded components, the test load shall be left in place for a period of at least 1 h. For components that carry dynamic loads such as impact loads, the load shall be left in place for a period consistent with the component's actual function. For materials that have strengths that are dependent on load duration, the test load shall be adjusted to account for the difference in load duration of the test compared to the expected duration of the design loads being considered. The component or structure shall be considered to have satisfied the test requirements where the following criteria are met:

1. During and after the test, the component or structure remains stable;
2. Within 24 h after removal of the test load, the component or structure has recovered at least 75% of the maximum deflection;
3. Deflection that remains after the load test (if any) does not substantively affect serviceability as determined by the registered design professional.

1.7 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

This section lists the consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

29 CFR (Code of Federal Regulations) Part 1910.1200. *OSHA Standards for General Industry*. Appendix A, with Amendments as of February 1, 2000. Occupational Safety and Health Administration, US Department of Labor, 2005.

Cited in: Section 1.2

@seismicisolation
@seismicisolation

CHAPTER 2
COMBINATIONS OF LOADS

2.1 GENERAL

Buildings and other structures shall be designed using the provisions of either Section 2.3 or 2.4. Where elements of a structure are designed by a particular material standard or specification, they shall be designed exclusively by either Section 2.3 or 2.4.

2.2 SYMBOLS

A_k = Load or load effect arising from extraordinary event, A
D = Dead load
D_i = Weight of ice
E = Earthquake load
F = Load caused by fluids with well-defined pressures and maximum heights other than those caused by groundwater pressure
F_a = Flood load
H = Load due to lateral earth pressure (including lateral earth pressure from fixed or moving surcharge loads), ground water pressure, or pressure of bulk materials
L = Live load
L_r = Roof live load
N = Notional load for structural integrity, Section 1.4
R = Rain load
S = Snow load
T = Cumulative effect of self-straining forces and effects arising from contraction or expansion resulting from environmental or operational temperature changes, shrinkage, moisture changes, creep in component materials, movement caused by differential settlement, or combinations thereof
W = Wind load
W_i = Wind-on-ice, determined in accordance with Chapter 10
W_T = Tornado load, determined in accordance with Chapter 32

2.3 LOAD COMBINATIONS FOR STRENGTH DESIGN

2.3.1 Basic Combinations Structures, components, and foundations shall be designed so that their design strength equals or exceeds the effects of the factored loads in the following combinations. Effects of one or more loads not acting shall be considered. Seismic load effects shall be combined loads, in accordance with Section 2.3.6. The most unfavorable effects from wind loads, tornado loads, and earthquake loads shall be considered, where appropriate, but they need not be assumed to act simultaneously. Refer to Sections 1.4, 2.3.6, 12.4, and 12.14.3 for the specific definition of the earthquake load effect, E. Each relevant strength limit state shall be investigated.

1a. $1.4D$
2a. $1.2D + 1.6L + (0.5L_r \text{ or } 0.3S \text{ or } 0.5R)$
3a. $1.2D + (1.6L_r \text{ or } 1.0S \text{ or } 1.6R) + (L \text{ or } 0.5W)$
4a. $1.2D + 1.0(W \text{ or } W_T) + L + (0.5L_r \text{ or } 0.3S \text{ or } 0.5R)$
5a. $0.9D + 1.0(W \text{ or } W_T)$

EXCEPTIONS:

1. The load factor on L in combinations 3a and 4a is permitted to equal 0.5 for all occupancies in which L_o in Chapter 4, Table 4.3-1, is less than or equal to 100 psf (4.78 kN/m^2), with the exception of garages or areas occupied as places of public assembly.
2. In combinations 2a and 4a, the companion load, S, shall be taken as either the flat roof snow load (p_f) or the sloped roof snow load (p_s).
3. Where using W_T in combination 4a, ($0.5L_r$ or $0.3S$ or $0.5R$) is permitted to be replaced with 0.5 (L_r or R).

Where fluid loads, F, are present, they shall be included with the same load factor as dead load, D, in combinations 1a through 4a. Where loads, H, are present, they shall be included as follows:

1. Where the effect of H adds to the principal load effect, include H with a load factor of 1.6;
2. Where the effect of H resists the principal load effect, include H with a load factor of 0.9, where the load H is permanent, or a load factor of 0 for all other conditions.

Each relevant strength limit state shall be investigated.

2.3.2 Load Combinations Including Flood Load When a structure is located in a flood zone (Section 5.3.1), the following load combinations shall be considered in addition to the basic combinations in Section 2.3.1:

In V-Zones or Coastal A-Zones:

4b. $1.2D + 1.0W + 2.0F_a + L + (0.5L_r \text{ or } 0.3S \text{ or } 0.5R)$
5b. $0.9D + 1.0W + 2.0F_a$

In noncoastal A-Zones:

4b. $1.2D + 0.5W + 1.0F_a + L + (0.5L_r \text{ or } 0.3S \text{ or } 0.5R)$
5b. $0.9D + 0.5W + 1.0F_a$

2.3.3 Load Combinations Including Atmospheric Ice and Wind-on-Ice Loads When a structure is subjected to atmospheric ice and wind-on-ice loads, the following load combinations shall be considered:

2b. $1.2D + 1.6L + 0.2D_i + 0.3S$
4c. $1.2D + L + D_i + W_i + 0.3S$
4d. $1.2D + D_i$
5c. $0.9D + D_i + W_i$

2.3.4 Load Combinations Including Self-Straining Forces and Effects Where the structural effects of T are expected to

@seismicisolation
@seismicisolation

adversely affect structural safety or performance, T shall be considered in combination with other loads. The load factor on T shall be established considering the uncertainty associated with the likely magnitude of the structural forces and effects, the probability that the maximum effect of T will occur simultaneously with other applied loadings, and the potential adverse consequences if the effect of T is greater than assumed. The load factor on T shall not have a value less than 1.0.

2.3.5 Load Combinations for Nonspecified Loads Where approved by the Authority Having Jurisdiction, the registered design professional is permitted to determine the combined load effect for strength design using a method that is consistent with the method on which the load combination requirements in Section 2.3.1 are based. Such a method must be probability based and must be accompanied by documentation regarding the analysis and collection of supporting data that are acceptable to the Authority Having Jurisdiction.

2.3.6 Basic Combinations with Seismic Load Effects When a structure is subject to seismic load effects, the following load combinations shall be considered in addition to the basic combinations in Section 2.3.1. The most unfavorable effects from seismic loads shall be investigated where appropriate, but they need not be considered to act simultaneously with wind or tornado loads.

Where the prescribed seismic load effect, $E = f(E_v, E_h)$, defined in Sections 12.4.2 or 12.14.3.1, is combined with the effects of other loads, the following seismic load combinations shall be used:

6. $1.2D + E_v + E_h + L + 0.15S$
7. $0.9D - E_v + E_h$

Where the seismic load effect with overstrength, $E_m = f(E_v, E_{mh})$, defined in Sections 12.4.3 or 12.14.3.2, is combined with the effects of other loads, the following seismic load combination for structures shall be used:

6. $1.2D + E_v + E_{mh} + L + 0.15S$
7. $0.9D - E_v + E_{mh}$

EXCEPTION:

1. The load factor on L in combination 6 is permitted to equal 0.5 for all occupancies in which L_o in Chapter 4, Table 4.3-1, is less than or equal to 100 psf (4.78 kN/m^2), with the exception of garages or areas occupied as places of public assembly.
2. In combination 6, the companion load, S, shall be taken as either the flat roof snow load (p_f) or the sloped roof snow load (p_s).

Where fluid loads, F, are present, they shall be included with the same load factor as dead load D in combinations 6 and 7.

Where loads, H, are present, they shall be included as follows:

1. Where the effect of H adds to the primary variable load effect, include H with a load factor of 1.6.
2. Where the effect of H resists the primary variable load effect, include H with a load factor of 0.9 where the load H is permanent, or a load factor of 0 for all other conditions.

2.3.7 Alternative Method for Loads from Water in Soil This section is permitted as an alternate for combining loads from soil and water in soil to the requirements in Section 2.3.1. The alternate is only permitted when using the loads defined in Section 3.3. For the purposes of this section, replace Symbol H from Section 2.2 with new symbols H_{eb} and H_w as follows:

H_{eb} = Load due to lateral earth pressure or pressure of bulk materials, including the effect of buoyancy from ground water pressure on the lateral pressure of earth or bulk materials but otherwise excluding ground water pressure

H_w = Load due to ground water pressure in soil

Where loads H_{eb} and H_w are present, they shall be included in the basic load combinations of Section 2.3.1 as follows:

1. Where the effect of H_{eb} adds to the principal load effect, compute H_{eb} based on the maximum ground water elevation and include H_{eb} with a load factor of 1.6.
2. Where the effect of H_{eb} resists the principal load effect, compute H_{eb} based on the minimum ground water elevation, and include H_{eb} with a load factor of 0.9 where the load H_{eb} is permanent or a load factor of 0 for all other conditions.
3. Where the effect of H_w adds to the principal load effect, include H_w based on the maximum ground water elevation with a load factor of 1.0.
4. Where the effect of H_w resists the principal load effect and the soil is permanent, compute H_w based on the minimum ground water elevation and include H_w with a load factor of 1.0, otherwise assign a load factor of 0.0 to H_w.

2.4 LOAD COMBINATIONS FOR ALLOWABLE STRESS DESIGN

2.4.1 Basic Combinations Loads listed herein shall be considered to act in the following combinations; whichever produces the most unfavorable effect on the building, foundation, or structural member shall be considered. Effects of one or more loads not acting shall be considered. Seismic load effects shall be combined with other loads, in accordance with Section 2.4.5. The most unfavorable effects from wind loads, tornado loads, and earthquake loads shall be considered, where appropriate, but they need not be assumed to act simultaneously. Refer to Sections 1.4, 2.4.5, 12.4, and 12.14.3 for the specific definition of the earthquake load effect, E.

Increases in allowable stress shall not be used with the loads or load combinations given in this standard unless it can be demonstrated that such an increase is justified by structural behavior caused by rate or duration of load.

1a. D
2a. $D + L$
3a. $D + (L_r$ or $0.7S$ or $R)$
4a. $D + 0.75L + 0.75(L_r$ or $0.7S$ or $R)$
5a. $D + 0.6(W$ or $W_T)$
6a. $D + 0.75L + 0.75(0.6(W$ or $W_T)) + 0.75(L_r$ or 0.7S or $R)$
7a. $0.6D + 0.6(W$ or $W_T)$

EXCEPTIONS:

1. In combinations 4a and 6a, the companion load, S, shall be taken as either the flat roof snow load (p_f) or the sloped roof snow load (p_s).
2. For nonbuilding structures in which the wind or tornado load is determined from force coefficients, C_f, identified in Figures 29.4-1, 29.4-2, and 29.4-3 and the projected area contributing wind or tornado force to a foundation element exceeds 1,000 ft^2 (93 m^2) on either a vertical or a horizontal plane, it shall be permitted to replace (W or W_T) with 0.9 (W or W_T) in combination 7a for design of the foundation, excluding anchorage of the structure to the foundation.

@seismicisolation

3. Where using W_T in combination 6a, 0.75 (L_r or 0.7S or R) is permitted to be replaced with 0.75 (L_r or R).

Where fluid loads, F, are present, they shall be included in combinations 1a through 6a, with the same factor as that used for dead load, D.

Where loads, H, are present, they shall be included as follows:

1. Where the effect of H adds to the principal load effect, include H with a load factor of 1.0.
2. Where the effect of H resists the principal load effect, include H with a load factor of 0.6 where the load H is permanent, or a load factor of 0 for all other conditions.

2.4.2 Load Combinations Including Flood Load When a structure is located in a flood zone, the following load combinations shall be considered:

In V-Zones or Coastal A-Zones:

5b. $D + 0.6W + 1.5F_a$
6b. $D + 0.75L + 0.75(0.6W) + 0.75(L_r \text{ or } 0.7S \text{ or } R) + 1.5F_a$
7b. $0.6D + 0.6W + 1.5F_a$

In noncoastal A-Zones:

5b. $D + 0.6W + 0.75F_a$
6b. $D + 0.75L + 0.75(0.6W) + 0.75(L_r \text{ or } 0.7S \text{ or } R) + 0.75F_a$
7b. $0.6D + 0.6W + 0.75F_a$

2.4.3 Load Combinations Including Atmospheric Ice and Wind-on-Ice Loads When a structure is subjected to atmospheric ice and wind-on-ice loads, the following load combinations shall be considered:

1b. $D + 0.7D_i$
2b. $D + L + 0.7D_i$
3b. $D + 0.7D_i + 0.7W_i + 0.7S$
7c. $0.6D + 0.7D_i + 0.7W_i$

2.4.4 Load Combinations Including Self-Straining Forces and Effects Where the structural effects of T are expected to adversely affect structural safety or performance, T shall be considered in combination with other loads. Where the maximum effect of load, T, is unlikely to occur simultaneously with the maximum effects of other variable loads, it shall be permitted to reduce the magnitude of T considered in combination with these other loads. The fraction of T considered in combination with other loads shall not be less than 0.75.

2.4.5 Basic Combinations with Seismic Load Effects When a structure is subject to seismic load effects, the following load combinations shall be considered in addition to the basic combinations and associated exceptions detailed in Section 2.4.1.

Where the prescribed seismic load effect, $E = f(E_v, E_h)$, defined in Section 12.4.2 or 12.14.3.1, is combined with the effects of other loads, the following seismic load combinations shall be used:

8. $1.0D + 0.7E_v + 0.7E_h$
9. $1.0D + 0.525E_v + 0.525E_h + 0.75L + 0.1S$
10. $0.6D - 0.7E_v + 0.7E_h$

Where the seismic load effect with overstrength, $E_m = f(E_v, E_{mh})$, defined in Section 12.4.3 or 12.14.3.2, is combined with the effects of other loads, the following seismic load combinations for structures not subject to flood or atmospheric ice loads shall be used:

8. $1.0D + 0.7E_v + 0.7E_{mh}$
9. $1.0D + 0.525E_v + 0.525E_{mh} + 0.75L + 0.1S$
10. $0.6D - 0.7E_v + 0.7E_{mh}$

Where allowable stress design methodologies are used with the seismic load effect defined in Section 12.4.3 or 12.14.3.2 and applied in load combinations 8, 9, or 10, allowable stresses are permitted to be determined using an allowable stress increase factor of 1.2. This increase shall not be combined with increases in allowable stresses or load combination reductions otherwise permitted by this standard, or the material reference document, except for increases caused by adjustment factors, in accordance with AWC NDS.

EXCEPTIONS:

1. In combination 9, the companion load, S, shall be taken as either the flat roof snow load (p_f) or the sloped roof snow load (p_s).
2. It shall be permitted to replace 0.6D with 0.9D in combination 10 for the design of special reinforced masonry shear walls where the walls satisfy the requirement of Section 14.4.2.

Where fluid loads, F, are present, they shall be included in combinations 8, 9, and 10, with the same factor as that used for dead load, D.

Where loads H are present, they shall be included as follows:

1. Where the effect of H adds to the primary variable load effect, include H with a load factor of 1.0.
2. Where the effect of H resists the primary variable load effect, include H with a load factor of 0.6 where the load H is permanent or a load factor of 0 for all other conditions.

2.5 LOAD COMBINATIONS FOR EXTRAORDINARY EVENTS

2.5.1 Applicability Where required by the owner or applicable code, strength and stability shall be checked to ensure that structures are capable of withstanding the effects of extraordinary (i.e., low probability) events, such as fires, explosions, and vehicular impact without disproportionate collapse.

2.5.2 Load Combinations

2.5.2.1 Capacity For checking the capacity of a structure or structural element to withstand the effect of an extraordinary event, the following gravity load combination shall be considered:

$$(0.9 \text{ or } 1.2)D + A_k + 0.5L + 0.15S \qquad (2.5\text{-}1)$$

in which A_k is the load or load effect resulting from the extraordinary event, A.

2.5.2.2 Residual Capacity For checking the residual load-carrying capacity of a structure or structural element following the occurrence of a damaging event, selected load-bearing elements identified by the registered design professional shall be notionally removed, and the capacity of the damaged structure shall be evaluated using the following gravity load combination:

$$(0.9 \text{ or } 1.2)D + 0.5L + 0.2(L_r \text{ or } 0.7S \text{ or } R) \qquad (2.5\text{-}2)$$

@seismicisolation
@seismicisolation

2.5.3 Stability Requirements Stability shall be provided for the structure as a whole and for each of its elements. Any method that considers the influence of second-order effects is permitted.

2.6 LOAD COMBINATIONS FOR GENERAL STRUCTURAL INTEGRITY LOADS

The notional loads, N, specified in Section 1.4 for structural integrity shall be combined with other loads, in accordance with Section 2.6.1 for strength design and Section 2.6.2 for allowable stress design.

2.6.1 Strength Design Notional Load Combinations

1. $1.2D + 1.0N + L + 0.15S$
2. $0.9D + 1.0N$

2.6.2 Allowable Stress Design Notional Load Combinations

1. $D + 0.7N$
2. $D + 0.75(0.7N) + 0.75L + 0.75$ (L_r or $0.7S$ or R)
3. $0.6D + 0.7N$

2.7 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

This section lists the consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

AWC NDS, *National Design Specification for Wood Construction, Including Supplements*, 2018 edition. American Wood Council, 2017.

Cited in: Section 2.4.5

@seismicisolation

CHAPTER 3
DEAD LOADS, SOIL LOADS, AND HYDROSTATIC PRESSURE

3.1 DEAD LOADS

3.1.1 Definition Dead loads consist of the weight of all materials of construction incorporated into the building including, but not limited to, walls, floors, roofs, ceilings, stairways, built-in partitions, finishes, cladding, and other similarly incorporated architectural and structural items, and the weight of fixed service equipment, including cranes and material handling systems.

3.1.2 Weights of Materials of Construction In determining dead loads for purposes of design, the actual weights of materials of construction shall be used. In the absence of definite information, values approved by the Authority Having Jurisdiction shall be used.

3.1.3 Weight of Fixed Service Equipment In determining dead loads for purposes of design, the weight of fixed service equipment, including the maximum weight of the contents of fixed service equipment, shall be included. The components of fixed service equipment that are variable, such as liquid contents and movable trays, shall not be used to counteract forces causing overturning, sliding, and uplift conditions in accordance with Section 1.3.6.

EXCEPTIONS:

1. Where force effects are the result of the presence of the variable components, the components are permitted to be used to counter those load effects. In such cases, the structure shall be designed for force effects with the variable components present and with them absent.
2. For the calculation of seismic force effects, the components of fixed service equipment that are variable, such as liquid contents and movable trays, need not exceed those expected during normal operation.

3.1.4 Vegetative and Landscaped Roofs The weight of all landscaping and hardscaping materials for vegetative and landscaped roofs shall be considered as dead load. The weight shall be computed considering both fully saturated soil and drainage layer materials, and fully dry soil and drainage layer materials, to determine the most severe load effects on the structure.

3.1.5 Solar Panels The weight of solar panels, their support system, and ballast shall be considered as dead load.

Table 3.2-1. Lateral Soil Load.

Description of Backfill Material	Unified Soil Classification	Lateral Soil Load* psf per foot of depth (kN/m^2 per meter of depth)	
		Active Pressure	At-rest Pressure
Well-graded, clean gravels, gravel-sand mixes	GW	35 (5.50)	60 (9.43)
Poorly graded, clean gravels, gravel-sand mixes	GP	35 (5.50)	60 (9.43)
Silty gravels, poorly graded gravel-sand mixes	GM	35 (5.50)	60 (9.43)
Clayey gravels, poorly graded gravel-and-clay mixes	GC	45 (7.07)	60 (9.43)
Well-graded, clean sands, gravel-sand mixes	SW	35 (5.50)	60 (9.43)
Poorly graded, clean sands, sand-gravel mixes	SP	35 (5.50)	60 (9.43)
Silty sands, poorly graded sand-silt mixes	SM	45 (7.07)	60 (9.43)
Sand-silt clay mix with plastic fines	SM-SC	85 (13.35)	100 (15.71)
Clayey sands, poorly graded sand-clay mixes	SC	85 (13.35)	100 (15.71)
Inorganic silts and clayey silts	ML	85 (13.35)	100 (15.71)
Mixture of inorganic silt and clay	ML-CL	85 (13.35)	100 (15.71)
Inorganic clays of low to medium plasticity	CL	100 (15.71)	100 (15.71)
Organic silts and silt-clays, low plasticity	OL	Unsuitable as backfill material	
Inorganic clayey silts, elastic silts	MH	Unsuitable as backfill material	
Inorganic clays of high plasticity	CH	Unsuitable as backfill material	
Organic clays and silty clays	OH	Unsuitable as backfill material	

*Lateral soil loads are given for moist conditions for the specified soils at their optimum densities. Actual field conditions shall govern. Submerged or saturated soil pressures shall include the weight of the buoyant soil plus the hydrostatic loads.

@seismicisolation

3.2 SOIL LOADS AND HYDROSTATIC PRESSURE

3.2.1 Lateral Pressures Structures below grade shall be designed to resist lateral soil loads from adjacent soil. If lateral soil loads are not given in a geotechnical report approved by the Authority Having Jurisdiction, then the lateral soil loads specified in Table 3.2-1 shall be used as the minimum design lateral soil loads. Foundation walls and other walls in which horizontal movement is restricted at the top shall be designed for at-rest pressure. Walls that are free to move and rotate at the top, such as retaining walls, shall be permitted to be designed for active pressure.

Where applicable, lateral pressure from fixed or moving surcharge loads shall be added to the lateral soil loads. When a portion or the whole of the adjacent soil is below a free-water surface, computations shall be based on the weight of the soil diminished by buoyancy, plus full hydrostatic pressure. The lateral pressure shall be increased if expansive soils are present at the site, as determined by a geotechnical investigation.

EXCEPTION: Foundation walls extending not more than 8 ft (2.44 m) below grade and laterally supported at the top by flexible diaphragms shall be permitted to be designed for active pressure.

3.2.2 Uplift Loads on Floors and Foundations Basement floors, slabs on ground, foundations, and similar approximately horizontal elements below grade shall be designed to resist uplift loads where applicable. The upward pressure of water shall be taken as the full hydrostatic pressure applied over the entire area. The hydrostatic load shall be determined based on the elevation of the underside of the element being evaluated.

Foundations, slabs on ground, and other components placed on expansive soils shall be designed to tolerate the movement or resist the upward loads caused by the expansive soils, or the expansive soil shall be removed or stabilized around and beneath the structure.

3.3 ALTERNATIVE METHOD FOR LOADS FROM WATER IN SOIL

This section is permitted as an alternative method to the requirements in Section 3.2. The alternative separates the computation of lateral loads from soil pressure from ground water pressure in soil. If this alternative is used, the load factors and combinations in Section 2.3.7 shall be used. The lateral pressure from soil shall be computed as required in Section 3.2.1, but the ground water pressure in soil shall be included in H_w, not in H. H_w for lateral and uplift loads shall be based upon the maximum ground water elevation. The maximum ground water elevation shall be established such that the annual probability of exceedance does not exceed the following values:

1. 0.0024 for Risk Category I
2. 0.0012 for Risk Category II
3. 0.0006 for Risk Category III
4. 0.0003 for Risk Category IV

For structures not located in a Design Flood Zone (see Chapter 5), the maximum ground water elevation need not be above the ground surface. Where lateral pressures are used to resist other variable loads and the soil is considered to be permanent, H_w shall be based upon the minimum ground water elevation. The minimum ground water elevation shall be established so that the annual probability of being at a lower elevation does not exceed the same values specified for the maximum ground water elevation. The minimum ground water elevation need not be taken below the lowest portion of the structure.

3.4 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

No consensus standards and other documents that shall be considered part of this standard are referenced in this chapter.

@seismicisolation
@seismicisolation

CHAPTER 4
LIVE LOADS

4.1 DEFINITIONS

The following definitions apply to the provisions of this chapter.

FIXED LADDER: A ladder that is permanently attached to a structure, building, or equipment.

GRAB BAR SYSTEM: A bar and associated anchorages and attachments to the structural system, for the support of body weight in locations such as toilets, showers, and tub enclosures.

GUARD SYSTEM: A component or assembly of components, including anchorages and attachments to the structural system, near open sides of an elevated surface for the purpose of minimizing the possibility of a fall from the elevated surface by people, equipment, or material.

HANDRAIL SYSTEM: A rail grasped by hand for guidance and support and associated anchorages and attachments to the structural system.

HELIPAD: A structural surface that is used for landing, taking off, taxiing, and parking helicopters.

LIVE LOAD: A load produced by the use and occupancy of the building or other structure that does not include construction or environmental loads, such as wind load, snow load, rain load, earthquake load, flood load, or dead load.

ROOF LIVE LOAD: A load on a roof produced (1) during maintenance by workers, equipment, and materials, and (2) during the life of the structure by movable objects, such as planters or other similar small decorative appurtenances that are not occupancy related. An occupancy-related live load on a roof such as rooftop assembly areas, rooftop decks, and vegetative or landscaped roofs with occupiable areas, is considered to be a live load rather than a roof live load.

SCREEN ENCLOSURE: A building or part thereof, in whole or in part self-supporting, having walls and a roof of insect or sun screening using fiberglass, aluminum, plastic, or similar lightweight netting material, which encloses an occupancy or use such as outdoor swimming pools, patios or decks, and horticultural and agricultural production facilities.

VEHICLE BARRIER SYSTEM: A system of components, including anchorages and attachments to the structural system near open sides or walls of garage floors or ramps, that acts as a restraint for vehicles.

4.2 LOADS NOT SPECIFIED

For occupancies or uses not designated in this chapter, the live load shall be determined in accordance with a method approved by the Authority Having Jurisdiction.

4.3 UNIFORMLY DISTRIBUTED LIVE LOADS

4.3.1 Required Live Loads The live loads used in the design of buildings and other structures shall be the maximum loads expected by the intended use or occupancy but shall not be less than the minimum uniformly distributed live loads required by Table 4.3-1.

4.3.2 Provision for Partitions In office buildings and in other buildings where partition locations are subject to change, provisions for partition weight shall be made, whether or not partitions are shown on the plans. The partition load shall not be less than 15 psf (0.72 kN/m^2) and shall not be reduced per Section 4.7.

EXCEPTION: A partition live load is not required where the minimum specified live load is 80 psf (3.83 kN/m^2) or greater.

4.3.3 Partial Loading The uniform live load applied only to a portion of a structure or member shall be accounted for if it produces a more unfavorable load effect than the uniform live load applied over the full structure or member. Uniform live loads applied to a portion of a structure or member are permitted to be reduced in accordance with Section 4.7.

4.3.3.1 Partial Loading of Roofs Where uniform roof live loads are reduced to less than 20 psf (0.96 kN/m^2) in accordance with Section 4.8.2 and are applied to the design of structural members arranged so as to create continuity, the reduced roof live load shall be applied to adjacent spans or to alternate spans, whichever produces the greatest unfavorable load effect.

4.3.4 Interior Walls and Partitions Interior walls and partitions that exceed 6 ft (1.83 m) in height, including their finish materials, shall have adequate strength and stiffness to resist the loads to which they are subjected but not less than a horizontal load of 5 psf (0.240 kN/m^2).

4.4 CONCENTRATED LIVE LOADS

Floors, roofs, and other similar surfaces shall be designed to support the uniformly distributed live loads prescribed in Section 4.3 or the concentrated live loads given in Table 4.3-1, whichever produces the greater load effects. Unless otherwise specified, the indicated concentrated load shall be assumed to be uniformly distributed over an area of 2.5 ft (762 mm) by 2.5 ft (762 mm) and shall be located so as to produce the maximum load effects in the members.

4.5 LOADS ON HANDRAIL, GUARD, GRAB BAR, AND VEHICLE BARRIER SYSTEMS, AND ON SHOWER SEATS AND FIXED LADDERS

4.5.1 Handrail and Guard Systems Handrail and guard systems shall be designed to resist a single concentrated load of 200 lb (0.89 kN) applied in any direction at any point on the

handrail or top rail to produce the maximum load effect on the element being considered and to transfer this load through the supports to the structure.

4.5.1.1 Uniform Load Handrail and guard systems shall also be designed to resist a load of 50 lb/ft (pound-force per linear foot) (0.73 kN/m) applied in any direction along the handrail or top rail and to transfer this load through the supports to the structure. This load need not be assumed to act concurrently with the concentrated load specified in Section 4.5.1.

EXCEPTIONS: The uniform load need not be considered for the following occupancies:

1. One- and two-family dwellings;
2. Factory, industrial, and storage occupancies in areas that are not accessible to the public and that serve an occupant load not greater than 50; and
3. Roofs not intended for occupancy.

4.5.1.2 Guard System Component Loads Balusters, panel fillers, and guard system infill components, including all rails except the handrail and the top rail, shall be designed to resist a horizontally applied normal load of 50 lb (0.22 kN) on an area not to exceed 12 in. × 12 in. (305 mm × 305 mm), including openings and space between rails and located so as to produce the maximum load effects. Reactions due to this loading are not required to be superimposed with the loads specified in Sections 4.5.1 and 4.5.1.1.

4.5.2 Grab Bar Systems and Shower Seats Grab bar systems and shower seats shall be designed to resist a single concentrated load of 250 lb (1.11 kN) applied in any direction at any point on the grab bar or shower seat to produce the maximum load effect.

4.5.3 Vehicle Barrier Systems Vehicle barrier systems for passenger vehicles shall be designed to resist a single

@seismicisolation

concentrated load of 6,000 lb (26.70 kN) applied horizontally in any direction to the barrier system and shall have anchorages or attachments capable of transferring this load to the structure. For design of the system, the load shall be assumed to act at heights between 1 ft 6 in. (460 mm) and 2 ft 3 in. (686 mm) above the floor or ramp surface, located to produce the maximum load effects. The load shall be applied on an area not to exceed 12 in. × 12 in. (305 mm × 305 mm). This load is not required to act concurrently with any handrail or guard system loadings specified in Section 4.5.1. Vehicle barrier systems in garages accommodating trucks and buses shall be designed in accordance with *AASHTO LRFD Bridge Design Specifications*.

4.5.4 Fixed Ladders Fixed ladders with rungs shall be designed to resist a single concentrated load of 300 lb (1.33 kN) applied at any point to produce the maximum load effect on the element being considered. The number and position of additional concentrated live load units shall be a minimum of 1 unit of 300 lb (1.33 kN) for every 10 ft (3.05 m) of ladder height.

Where rails of fixed ladders extend above a floor or platform at the top of the ladder, each side rail extension shall be designed to resist a single concentrated live load of 100 lb (0.445 kN) applied in any direction at any height up to the top of the side rail extension. Ships ladders with treads instead of rungs shall be designed to resist the stair loads given in Table 4.3-1.

4.6 IMPACT LOADS

4.6.1 General The live loads specified in Sections 4.3 through 4.5 shall be assumed to include adequate allowance for ordinary impact conditions. Provision shall be made in the structural design for uses and loads that involve unusual vibration and impact forces.

4.6.2 Elevators All elements subject to dynamic loads from elevators shall be designed for impact loads and deflection limits prescribed by ASME A17.1.

4.6.3 Machinery For the purpose of design, the weight of machinery and moving loads shall be increased as follows to allow for impact: (1) light machinery, shaft- or motor-driven, 20%; and (2) reciprocating machinery or power-driven units, 50%. All percentages shall be increased where specified by the manufacturer.

4.6.4 Elements Supporting Hoists for Façade Access and Building Maintenance Equipment Structural elements that support hoists for façade access and building maintenance equipment shall be designed for a live load of 2.5 times the rated load of the hoist or the stall load of the hoist, whichever is larger.

4.6.5 Fall Arrest, Lifeline, and Rope Descent System Anchorages Fall arrest, lifeline, and rope descent system anchorages and the structural elements that support these anchorages shall be designed for a live load of 3,100 lb (13.8 kN) for each attached line in any direction that the load may be applied.

Anchorages of horizontal lifelines and the structural elements that support the anchorages shall be designed for the maximum tension that develops in the horizontal lifeline from these live loads.

4.7 REDUCTION IN UNIFORM LIVE LOADS

4.7.1 General Except for roof uniform live loads, all other minimum uniformly distributed live loads, L_o, in Table 4.3-1, are permitted to be reduced in accordance with the requirements of Sections 4.7.2 through 4.7.6.

4.7.2 Reduction in Uniform Live Loads Subject to the limitations of Sections 4.7.3 through 4.7.6, members for which the value of $K_{LL}A_T$ is 400 ft^2 (37.16 m^2) or more are permitted to be designed for a reduced uniform live load in accordance with the following formula:

$$L = L_o \left(0.25 + \frac{15}{\sqrt{K_{LL}A_T}}\right) \quad (4.7\text{-}1)$$

$$L = L_o \left(0.25 + \frac{4.57}{\sqrt{K_{LL}A_T}}\right) \quad (4.7\text{-}1.\text{SI})$$

where

L = Reduced design live load per ft^2 (m^2) of area supported by the member;
L_o = Unreduced design live load per ft^2 (m^2) of area supported by the member (see Table 4.3-1);
K_{LL} = Live load element factor (see Table 4.7-1); and
A_T = Tributary area in ft^2 (m^2).

L shall not be less than $0.50L_o$ for members supporting one floor, and L shall not be less than $0.40L_o$ for members supporting two or more floors.

4.7.3 Heavy Live Loads Live loads that exceed 100 lb/ft^2 (4.79 kN/m^2) shall not be reduced.

EXCEPTION: Live loads for members supporting two or more floors are permitted to be reduced by a maximum of 20%, but the reduced live load shall not be less than L as calculated in Section 4.7.2.

4.7.4 Passenger Vehicle Garages The live loads shall not be reduced in passenger vehicle garages.

EXCEPTION: Live loads for members supporting two or more floors are permitted to be reduced by a maximum of 20%, but the reduced live load shall not be less than L as calculated in Section 4.7.2.

4.7.5 Assembly Area Loads Live loads shall not be reduced in assembly areas.

Table 4.7-1. Live Load Element Factor, K_{LL}.

Element	K_{LL}*
Interior columns	4
Exterior columns without cantilever slabs	4
Edge columns with cantilever slabs	3
Corner columns with cantilever slabs	2
Edge beams without cantilever slabs	2
Interior beams	2
All other members not identified, including	1
Edge beams with cantilever slabs	
Cantilever beams	
One-way slabs	
Two-way slabs	
Members without provisions for continuous shear transfer normal to their span	

*In lieu of the preceding values, K_{LL} is permitted to be calculated.

@seismicisolation

4.7.6 Limitations on One-Way Slabs The tributary area, A_T, for one-way slabs shall not exceed an area defined by the slab span times a width normal to the span of 1.5 times the slab span.

4.8 REDUCTION IN UNIFORM ROOF LIVE LOADS

4.8.1 General The minimum uniformly distributed roof live loads, L_o, in Table 4.3-1, are permitted to be reduced in accordance with the requirements of Sections 4.8.2 and 4.8.3.

4.8.2 Ordinary Roofs, Awnings, and Canopies Ordinary flat, pitched, and curved roofs, and awning and canopies other than those of fabric construction supported by a skeleton structure, are permitted to be designed for a reduced uniform roof live load, as specified in Equation (4.8-1), or other controlling combinations of loads, as specified in Chapter 2, whichever produces the greater load effect. In structures such as greenhouses, where special scaffolding is used as a work surface for workers and materials during maintenance and repair operations, a lower roof load than specified in Equation (4.8-1) shall not be used unless approved by the Authority Having Jurisdiction. On such structures, the minimum roof live load shall be 12 psf (0.58 kn/m^2).

$$L_r = L_o R_1 R_2 \quad \text{where} \quad 12 \le L_r \le 20 \tag{4.8-1}$$

$$L_r = L_o R_1 R_2 \quad \text{where} \quad 0.58 \le L_r \le 0.96 \tag{4.8-1.SI}$$

where L_r is the reduced roof live load per ft^2 (m^2) of horizontal projection supported by the member, and L_o is the unreduced design roof live load per ft^2 (m^2) of horizontal projection supported by the member (see Table 4.3-1).

The reduction factors R_1 and R_2 shall be determined as follows:

$$R_1 = \begin{cases} 1 & \text{for} \quad A_T \le 200 \text{ ft}^2 \\ 1.2 - 0.001A_T & \text{for} \quad 200 \text{ ft}^2 < A_T < 600 \text{ ft}^2 \\ 0.6 & \text{for} \quad A_T \ge 600 \text{ ft}^2 \end{cases}$$

in SI:

$$R_1 = \begin{cases} 1 & \text{for} \quad A_T \le 18.58 \text{ m}^2 \\ 1.2 - 0.011A_T & \text{for} \quad 18.58 \text{ m}^2 < A_T < 55.74 \text{ m}^2 \\ 0.6 & \text{for} \quad A_T \ge 55.74 \text{ m}^2 \end{cases}$$

where A_T is the tributary area in ft^2 (m^2) supported by the member and

$$R_2 = \begin{cases} 1 & \text{for} \quad F \le 4 \\ 1.2 - 0.05F & \text{for} \quad 4 < F < 12 \\ 0.6 & \text{for} \quad F \ge 12 \end{cases}$$

where, for a pitched roof, F is the number of inches of rise per foot (in SI: $F = 0.12 \times$ slope, with slope expressed in percentage points) and, for an arch or dome, F is the rise-to-span ratio multiplied by 32.

4.8.3 Occupiable Roofs Roofs that have an occupancy function, such as roof gardens or other special purposes, are permitted to have their uniformly distributed live load reduced in accordance with the requirements of Section 4.7.

Roofs used for other special purposes shall be designed for appropriate loads as approved by the Authority Having Jurisdiction.

4.9 CRANE LOADS

4.9.1 General The crane live load shall be the rated capacity of the crane. Design loads for the runway beams, including connections and support brackets, of moving bridge cranes and monorail cranes shall include the maximum wheel loads of the crane and the vertical impact, lateral, and longitudinal forces induced by the moving crane.

4.9.2 Maximum Wheel Load The maximum wheel loads shall be the wheel loads produced by the weight of the bridge, as applicable, plus the sum of the rated capacity and the weight of the trolley with the trolley positioned on its runway at the location where the resulting load effect is maximized.

4.9.3 Vertical Impact Force The maximum wheel loads of the crane determined in accordance with Section 4.9.2 shall be increased by the percentages shown in the following text to account for the effects of vertical impact or vibration:

Monorail cranes (powered)	25%
Bridge crane service class D, E, or F	25%
Bridge crane service class A, B, or C	10%
Cranes with hand-geared bridge, trolley, and hoist	0%

4.9.3.1 Bridge Crane Service Class For the purpose of determining the vertical impact force, one of the following bridge crane service classes shall be assigned based on the actual service conditions, including the frequency of use, variability in load lifted, and the operation speed.

Bridge Crane Service Class A (Standby or infrequent service): This service class shall include cranes used in installations such as powerhouses, public utilities, turbine rooms, motor rooms, and transformer stations where precise handling of equipment at slow speeds is required and cranes are infrequently used or are idled for long periods. Full rated loads shall be handled for initial installation of equipment and for infrequent maintenance.

Bridge Crane Service Class B (Light service): This service class shall include cranes used in repair shops, light assembly operations, service buildings, light warehousing, etc. where service requirements are light and the speed is slow. Loads are permitted to vary, but full rated loads shall occur only occasionally, with two to five lifts per hour, averaging 10 ft (3.05 m) per lift.

Bridge Crane Service Class C (Moderate service): This service class shall include cranes used in machine shops or paper mill machine rooms, etc. where service requirements are moderate. In this type of service, the crane shall handle loads which average 50% of the rated capacity with five to ten lifts per hour, averaging 15 ft (4.6 m), not over 50% of the lifts at rated capacity.

Bridge Crane Service Class D (Heavy service): This service class shall include cranes used in heavy machine shops, foundries, fabricating plants, steel warehouses, container yards, lumber mills, etc., and the standard duty bucket and magnet operations where heavy duty production is required. In this type of service, the crane shall handle loads approaching 50% of the rated capacity constantly during the working period. High speeds are used for this type of service with 10 to 20 lifts per hour averaging 15 ft (4.6 m), not over 65% of the lifts at rated capacity.

Bridge Crane Service Class E (Severe service): This service class shall include cranes capable of handling loads approaching rated capacity throughout its life. Applications include magnet, bucket, magnet/bucket combination cranes for scrap yards, cement mills, lumber mills, fertilizer plants, container handling, etc., with 20 or more lifts per hour at or near the rated capacity.

@seismicisolation

Bridge Crane Service Class F (Continuous severe service): This service class shall include cranes capable of handling loads approaching rated capacity continuously under severe service conditions throughout its life. Applications include custom designed specialty cranes essential to performing the critical work tasks affecting the total production facility. These cranes shall provide the highest reliability with special attention to ease of maintenance features.

4.9.4 Lateral Force The lateral force on crane runway beams with electrically powered trolleys shall be calculated as 20% of the sum of the rated capacity of the crane and the weight of the hoist and trolley. The lateral force shall be assumed to act horizontally at the traction surface of a runway beam, in either direction perpendicular to the beam, and shall be distributed with due regard to the lateral stiffness of the runway beam and supporting structure.

4.9.5 Longitudinal Force The longitudinal force on crane runway beams, except for bridge cranes with hand-geared bridges, shall be calculated as 10% of the maximum wheel loads of the crane. The longitudinal force shall be assumed to act horizontally at the traction surface of a runway beam in either direction parallel to the beam.

4.10 GARAGE AND VEHICULAR FLOOR LOADS

4.10.1 Passenger Vehicle Garages Floors in garages and portions of a building used for the storage of motor vehicles shall be designed for the uniformly distributed live loads of Table 4.3-1 or the following concentrated load: (1) for garages restricted to passenger vehicles accommodating not more than nine passengers, 3,000 lb (13.35 kN) acting on an area of 4.5 in. × 4.5 in. (114 mm × 114 mm); and (2) for mechanical parking structures without slab or deck that are used for storing passenger vehicles only 2,250 lb (10 kN) per wheel.

4.10.2 Truck and Bus Garages Live loads in garages and portions of a building used for the storage of trucks and buses shall be in accordance with the *AASHTO LRFD Bridge Design Specifications*; however, provisions for fatigue and dynamic load allowance therein are not required to be applied.

EXCEPTION: The vehicular live loads and load placement in garages and portions of a building used for the storage of trucks or buses are permitted to be determined using the actual vehicle weights for the vehicles allowed onto the garage floors, provided that such loads and placement are based on rational engineering principles and are approved by the Authority Having Jurisdiction. The load effects from the actual vehicle weights shall not be less than the effects from a uniform live load of 50 psf (2.40 kN/m^2). This live load shall not be reduced.

4.10.3 Sidewalks, Vehicular Driveways, and Yards Subject to Trucking Uniform loads for sidewalks, vehicular driveways, and yards subject to truck loads, other than that provided in Table 4.3-1, shall also be considered where appropriate, in accordance with an approved method which contains provisions for truck loads. The concentrated wheel load provided in Table 4.3-1 shall be applied on an area of 4.5 in. × 4.5 in. (114 mm × 114 mm).

4.10.4 Emergency Vehicle Loads Where a structure or portions of a structure are accessed by fire department vehicles and other emergency vehicles, those portions of the structure subjected to such loads shall be designed for one of the following:

(a) The actual operational loads, including the total vehicle load, the individual wheel loads, and the outrigger reactions, whichever produces the greater load effects, as stipulated and approved by the Authority Having Jurisdiction. The loads shall include the combined weight of the vehicle and equipment. The total vehicle load, individual wheel loads, and outrigger reactions do not act concurrently.
(b) The design truck and design tandem live loads in the *AASHTO LRFD Bridge Design Specifications*. The design truck and the design tandem need not be assumed to act concurrently. The AASHTO provisions for fatigue and dynamic load allowance are not required to be applied.

Emergency vehicle loads need not be assumed to act concurrently with other uniform live loads.

EXCEPTION: Emergency vehicle loads need not be considered for portions of the structure where physical barriers such as bollards, vehicle barriers, or overhead clearance bars restrict emergency vehicle access.

4.11 HELIPAD LOADS

4.11.1 General The live loads shall not be reduced. The labeling of helicopter capacity shall be as required by the Authority Having Jurisdiction.

4.11.2 Concentrated Helicopter Loads Two single concentrated loads, 8 ft (2.44 m) apart, shall be applied on the landing area (representing the helicopter's two main landing gear, whether skid type or wheeled type), each having a magnitude of 0.75 times the maximum takeoff weight of the helicopter and located to produce the maximum load effect on the structural elements under consideration. The concentrated loads shall be applied over an area of 8 in. × 8 in. (200 mm × 200 mm) and are not required to act concurrently with other uniform or concentrated live loads.

A single concentrated load of 3,000 lb (13.35 kN) shall be applied over an area of 4.5 in. × 4.5 in. (114 mm × 114 mm), located so as to produce the maximum load effects on the structural elements under consideration. The concentrated load is not required to act concurrently with other uniform or concentrated live loads.

4.12 UNINHABITABLE ATTICS

4.12.1 Uninhabitable Attics without Storage In residential occupancies, uninhabitable attic areas without storage are those where the maximum clear height between the joist and rafter is less than 42 in. (1,067 mm) or where there are not two or more adjacent trusses with web configurations capable of accommodating an assumed rectangle 42 in. (1,067 mm) in height by 24 in. (610 mm) in width, or greater, within the plane of the trusses. The live load in Table 4.3-1 need not be assumed to act concurrently with any other live load requirement.

4.12.2 Uninhabitable Attics with Storage In residential occupancies, uninhabitable attic areas with storage are those where the maximum clear height between the joist and rafter is 42 in. (1,067 mm) or greater or where there are two or more adjacent trusses with web configurations capable of accommodating an assumed rectangle 42 in. (1,067 mm) in height by 24 in. (610 mm) in width, or greater, within the

@seismicisolation

plane of the trusses. For attics constructed of trusses, the live load in Table 4.3-1 need only be applied to those portions of the bottom chords where both of the following conditions are met:

- The attic area is accessible from an opening not less than 20 in. (508 mm) in width by 30 in. (762 mm) in length that is located where the clear height in the attic is a minimum of 30 in. (762 mm); and
- The slope of the truss bottom chord is no greater than 2 units vertical to 12 units horizontal (9.5% slope).

The remaining portions of the bottom chords shall be designed for a uniformly distributed concurrent live load of not less than 10 lb/ft^2 (0.48 kN/m^2).

4.13 LIBRARY STACK ROOMS

The live loading for library stack rooms provided in Table 4.3-1 applies to stack room floors that support nonmobile, double-faced library book stacks subject to the following limitations:

1. The nominal book stack unit height shall not exceed 90 in. (2,290 mm);
2. The nominal shelf depth shall not exceed 12 in. (305 mm) for each face;
3. Parallel rows of double-faced book stacks shall be separated by aisles not less than 36 in. (914 mm) wide.

4.14 SEATING FOR ASSEMBLY USES

In addition to the vertical live loads provided in Table 4.3-1 for bleachers, folding and telescopic seating, and grandstands, and for stadiums and arenas with fixed seats fastened to the floor, the design shall include horizontal swaying forces applied to each row of the seats as follows:

- 24 lb per linear ft (0.35 kN/m) of seat applied in a direction parallel to each row of seats; and
- 10 lb per linear ft (0.15 kM/m) of seat applied in a direction perpendicular to each row of seats.

The parallel and perpendicular horizontal swaying forces need not be applied simultaneously.

4.15 STAIR TREADS

The concentrated load on stair treads provided in Table 4.3-1 for stair and exit ways, and for stairs in one- and two-family dwellings, shall be applied on an area of 2 in. × 2 in. (50 mm × 50 mm) and is to be applied nonconcurrently with the uniform load.

4.16 SOLAR PANEL LOADS

4.16.1 Roof Loads at Solar Panels Roof structures that support solar panel systems shall be designed to resist each of the following conditions:

1. The uniform and concentrated roof live loads specified in Table 4.3-1 with the solar panel system dead loads.

   EXCEPTION: The roof live load need not be applied to the area covered by solar panels where the clear space between the panels and the roof surface is 24 in. (610 mm) or less.
2. The uniform and concentrated roof live loads specified in Table 4.3-1 without the solar panel system present.

4.16.2 Load Combination Roof systems that provide support for solar panel systems shall be designed for the load combinations specified in Chapter 2.

4.16.3 Open-Grid Roof Structures Supporting Solar Panels Structures with open-grid framing and no roof deck or sheathing supporting solar panel systems shall be designed to support the uniform and concentrated roof live loads specified in Table 4.3-1, except that the uniform roof live load shall be permitted to be reduced to 12 psf (0.57 kN/m^2).

4.17 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

This section lists the consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

CHAPTER 5
FLOOD LOADS

5.1 GENERAL

The provisions of this section apply to buildings and other structures located in areas prone to flooding as defined on a flood hazard map.

5.2 DEFINITIONS

The following definitions apply to the provisions of this chapter:

APPROVED: Acceptable to the Authority Having Jurisdiction.

BASE FLOOD: The flood having a 1% chance of being equaled or exceeded in any given year.

BASE FLOOD ELEVATION (BFE): The elevation of flooding, including wave height, having a 1% chance of being equaled or exceeded in any given year.

BREAKAWAY WALL: Any type of wall subject to flooding that is not required to provide structural support to a building or other structure and that is designed and constructed such that, under base flood or lesser flood conditions, it will collapse in such a way that (1) it allows the free passage of floodwaters, and (2) it does not damage the structure or supporting foundation system.

COASTAL A-ZONE: An area within a special flood hazard area, landward of a V-Zone or landward of an open coast without mapped V-Zones. To be classified as a Coastal A-Zone, the principal source of flooding must be astronomical tides, storm surges, seiches, or tsunamis, not riverine flooding, and the potential for breaking wave heights greater than or equal to 1.5 ft (0.46 m) must exist during the base flood.

COASTAL HIGH HAZARD AREA (V-ZONE): An area within a special flood hazard area, extending from offshore to the inland limit of a primary frontal dune along an open coast, and any other area that is subject to high-velocity wave action from storms or seismic sources. This area is designated on flood insurance rate maps (FIRMs) as V, VE, VO, or V1-30.

DESIGN FLOOD: The greater of the following two flood events: (1) the base flood, affecting those areas identified as special flood hazard areas on the community's FIRM; or (2) the flood corresponding to the area designated as a flood hazard area on a community's flood hazard map or otherwise legally designated.

DESIGN FLOOD ELEVATION (DFE): The elevation of the design flood, including wave height, relative to the datum specified on a community's flood hazard map.

FLOOD HAZARD AREA: The area subject to flooding during the design flood.

FLOOD HAZARD MAP: The map delineating flood hazard areas adopted by the Authority Having Jurisdiction.

FLOOD INSURANCE RATE MAP (FIRM): An official map of a community on which the Federal Insurance and Mitigation Administration has delineated both special flood hazard areas and the risk premium zones applicable to the community.

SPECIAL FLOOD HAZARD AREA (AREA OF SPECIAL FLOOD HAZARD): The land in the floodplain subject to a 1% or greater chance of flooding in any given year. These areas are delineated on a community's FIRM as A-Zones (A, AE, A1-30, A99, AR, AO, or AH) or V-Zones (V, VE, VO, or V1-30).

5.3 DESIGN REQUIREMENTS

5.3.1 Design Loads Structural systems of buildings or other structures shall be designed, constructed, connected, and anchored to resist flotation, collapse, and permanent lateral displacement due to action of flood loads associated with the design flood (see Section 5.3.3) and other loads in accordance with the load combinations of Chapter 2.

5.3.2 Erosion and Scour The effects of erosion and scour shall be included in the calculation of loads on buildings and other structures in flood hazard areas.

5.3.3 Loads on Breakaway Walls Walls and partitions required by ASCE/SEI 24 to break away, including their connections to the structure, shall be designed for the largest of the following loads acting perpendicular to the plane of the wall:

1. Wind load specified in Chapter 26,
2. Earthquake load specified in Chapter 12, and
   10 psf (0.48 kN/m^2).

The loading at which breakaway walls are intended to collapse shall not exceed 20 psf (0.96 kN/m^2) unless the design meets the following conditions:

1. Breakaway wall collapse is designed to result from a flood load less than that which occurs during the base flood.
2. The supporting foundation and the elevated portion of the building shall be designed against collapse, permanent lateral displacement, and other structural damage due to the effects of flood loads in combination with other loads as specified in Chapter 2.

5.4 LOADS DURING FLOODING

5.4.1 Load Basis In flood hazard areas, the structural design shall be based on the design flood.

5.4.2 Hydrostatic Loads Hydrostatic loads caused by a depth of water to the level of the DFE shall be applied over all surfaces involved, both above and below ground level, except that for surfaces exposed to free water, the design depth shall be increased by 1 ft (0.30 m).

@seismicisolation
@seismicisolation

Reduced uplift and lateral loads on surfaces of enclosed spaces below the DFE shall apply only if provision is made for entry and exit of floodwater.

5.4.3 Hydrodynamic Loads Dynamic effects of moving water shall be determined by a detailed analysis utilizing basic concepts of fluid mechanics.

EXCEPTION: Where water velocities do not exceed 10 ft/s (3.05 m/s), dynamic effects of moving water shall be permitted to be converted into equivalent hydrostatic loads by increasing the DFE for design purposes by an equivalent surcharge depth, d_h, on the headwater side and above the ground level only, equal to

$$d_h = \frac{aV^2}{2g} \tag{5.4-1}$$

where

V = Average velocity of water, ft/s (m/s);
g = Acceleration due to gravity, 32.2 ft/s^2 (9.81 m/s^2); and
a = Coefficient of drag or shape factor (not less than 1.25).

The equivalent surcharge depth shall be added to the DFE design depth and the resultant hydrostatic pressures applied to, and uniformly distributed across, the vertical projected area of the building or structure that is perpendicular to the flow. Surfaces parallel to the flow or surfaces wetted by the tailwater shall be subject to the hydrostatic pressures for depths to the DFE only.

5.4.4 Wave Loads Wave loads shall be determined by one of the following three methods: (1) by using the analytical procedures outlined in this section, (2) by more advanced numerical modeling procedures, or (3) by laboratory test procedures (physical modeling).

Wave loads are those loads that result from water waves propagating over the water surface and striking a building or other structure. Design and construction of buildings and other structures subject to wave loads shall account for the following loads: waves breaking on any portion of the building or structure; uplift forces caused by shoaling waves beneath a building or structure, or portion thereof; wave runup striking any portion of the building or structure; wave-induced drag and inertia forces; and wave-induced scour at the base of a building or structure, or its foundation. Wave loads shall be included for both V-Zones and A-Zones. In V-Zones, waves are 3 ft (0.91 m) high, or higher; in coastal floodplains landward of the V-Zone, waves are less than 3 ft (0.91 m) high.

Nonbreaking and broken wave loads shall be calculated using the procedures described in Sections 5.4.2 and 5.4.3 that show how to calculate hydrostatic and hydrodynamic loads.

Breaking wave loads shall be calculated using the procedures described in Sections 5.4.4.1 through 5.4.4.4. Breaking wave heights used in the procedures described in Sections 5.4.4.1 through 5.4.4.4 shall be calculated for V-Zones and Coastal A-Zones using Equations (5.4-2) and (5.4-3):

$$H_b = 0.78 d_s \tag{5.4-2}$$

where H_b is the breaking wave height in ft (m), and d_s is the local still water depth in ft (m).

The local still water depth shall be calculated using Equation (5.4-3), unless more advanced procedures or laboratory tests permitted by this section are used:

$$d_s = 0.65(BFE - G) \tag{5.4-3}$$

where BFE is in ft (m), and G is ground elevation in ft (m).

5.4.4.1 Breaking Wave Loads on Vertical Pilings and Columns The net force resulting from a breaking wave acting on a rigid vertical pile or column shall be assumed to act at the still water elevation and shall be calculated by the following:

$$F_D = 0.5\gamma_w C_D D H_b^2 \tag{5.4-4}$$

where

F_D = Net wave force, lb (kN);
γ_w = Unit weight of water, lb/ft^3 (kN/m^3), = 62.4 lb/ft^3 (9.80 kN/m^3) for freshwater and 64.0 lb/ft^3 (10.05 kN/m^3) for saltwater;
C_D = Coefficient of drag for breaking waves, = 1.75 for round piles or columns and = 2.25 for square piles or columns;
D = Pile or column diameter, ft (m) for circular sections, or for a square pile or column, 1.4 times the width of the pile or column, ft (m); and
H_b = Breaking wave height, ft (m).

5.4.4.2 Breaking Wave Loads on Vertical Walls Maximum pressures and net forces resulting from a normally incident breaking wave (depth limited in size, with $H_b = 0.78 d_s$) acting on a rigid vertical wall shall be calculated by the following:

$$P_{\max} = C_p \gamma_w d_s + 1.2\gamma_w d_s \tag{5.4-5}$$

and

$$F_t = 1.1 C_p \gamma_w d_s^2 + 2.4\gamma_w d_s^2 \tag{5.4-6}$$

where

$P_{\max}$ = Maximum combined dynamic ($C_p \gamma_w d_s$) and static ($1.2\gamma_w d_s$) wave pressures, also referred to as shock pressures, lb/ft^2 (kN/m^2);
F_t = Net breaking wave force per unit length of structure, also referred to as shock, impulse, or wave impact force, lb/ft (kN/m), acting near the still water elevation;
C_p = Dynamic pressure coefficient ($1.6 < C_p < 3.5$) (see Table 5.4-1);
γ_w = Unit weight of water, lb/ft^3 (kN/m^3), = 62.4 lb/ft^3 (9.80 kN/m^3) for freshwater and 64.0 lb/ft^3 (10.05 kN/m^3) for saltwater; and
d_s = Still water depth, ft (m), at base of building or other structure where the wave breaks.

This procedure assumes the vertical wall causes a reflected or standing wave against the waterward side of the wall with the crest of the wave at a height of $1.2 d_s$ above the still water level. Thus, the dynamic static and total pressure distributions against the wall are as shown in Figure 5.4-1.

This procedure also assumes the space behind the vertical wall is dry, with no fluid balancing the static component of the wave force on the outside of the wall. If free water exists behind the wall, a portion of the hydrostatic component of the wave pressure and force disappears (see Figure 5.4-2) and the net force shall be computed by Equation (5.4-7) [the maximum combined wave pressure is still computed with Equation (5.4-5)]:

$$F_t = 1.1 C_p \gamma_w d_s^2 + 1.9\gamma_w d_s^2 \tag{5.4-7}$$

where

F_t = Net breaking wave force per unit length of structure, also referred to as shock, impulse, or wave impact force, lb/ft (kN/m), acting near the still water elevation;

@seismicisolation

C_p = Dynamic pressure coefficient ($1.6 < C_p < 3.5$) (see Table 5.4-1);
γ_w = Unit weight of water, lb/ft^3 (kN/m^3), = 62.4 lb/ft^3 (9.80 kN/m^3) for freshwater and 64.0 lb/ft^3 (10.05 kN/m^3) for saltwater; and
d_s = Still water depth, ft (m) at base of building or other structure where the wave breaks.

5.4.4.3 Breaking Wave Loads on Nonvertical Walls Breaking wave forces given by Equations (5.4-6) and (5.4-7) shall be modified in instances where the walls or surfaces upon which the breaking waves act are nonvertical. The horizontal component of breaking wave force shall be given by

$$F_{nv} = F_t \sin^2\alpha \tag{5.4-8}$$

where

F_{nv} = Horizontal component of breaking wave force, lb/ft (kN/m);
F_t = Net breaking wave force acting on a vertical surface, lb/ft (kN/m); and
α = Vertical angle between nonvertical surface and the horizontal.

Table 5.4-1. Value of Dynamic Pressure Coefficient, C_p.

Risk Category*	C_p
I	1.6
II	2.8
III	3.2
IV	3.5

*For risk category, see Table 1.5-1.

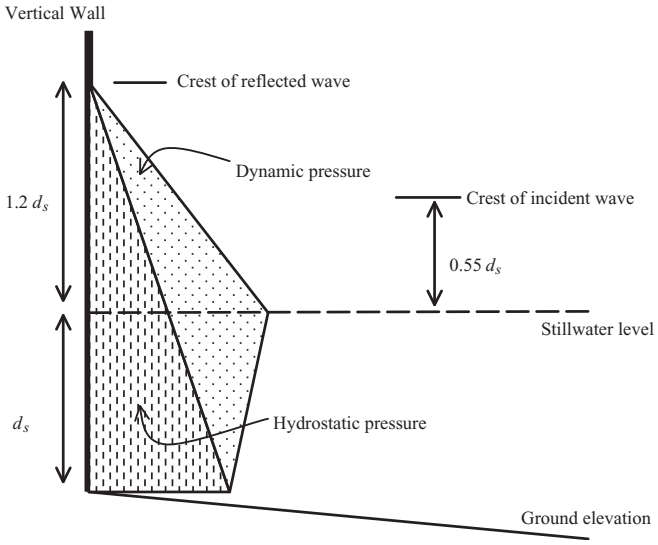

Figure 5.4-1. Normally Incident Breaking Wave Pressures against a Vertical Wall (Space behind Vertical Wall Is Dry).

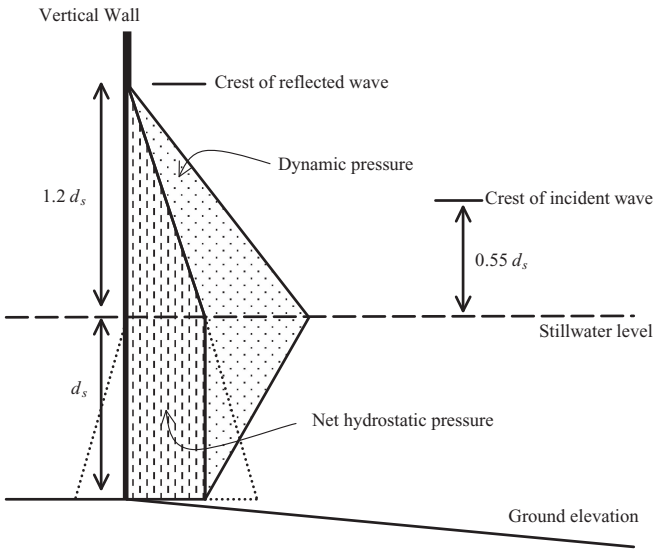

Figure 5.4-2. Normally Incident Breaking Wave Pressures against a Vertical Wall (Still Water Level Equal on Both Sides of Wall).

5.4.4.4 Breaking Wave Loads from Obliquely Incident Waves Breaking wave forces given by Equations (5.4-6) and (5.4-7) shall be modified in instances where waves are obliquely incident. Breaking wave forces from non-normally incident waves shall be given by

$$F_{oi} = F_t \sin^2\alpha \tag{5.4-9}$$

where

F_{oi} = Horizontal component of obliquely incident breaking wave force, lb/ft (kN/m);
F_t = Net breaking wave force (normally incident waves) acting on a vertical surface, lb/ft (kN/m); and
α = Horizontal angle between the direction of wave approach and the vertical surface.

5.4.5 Impact Loads Impact loads result from debris, ice, and any object transported by floodwaters striking against buildings and structures or parts thereof. Impact loads shall be determined using a rational approach as concentrated loads acting horizontally at the most critical location at or below the DFE.

5.5 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

This section lists the consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

CHAPTER 6
TSUNAMI LOADS AND EFFECTS

6.1 GENERAL REQUIREMENTS

6.1.1 Scope The following buildings and other structures located within the Tsunami Design Zone shall be designed for the effects of Maximum Considered Tsunami, including hydrostatic and hydrodynamic forces, waterborne debris accumulation and impact loads, subsidence, and scour effects in accordance with this chapter:

a Tsunami Risk Category IV buildings and structures;
b Tsunami Risk Category III buildings and structures with inundation depth greater than 3 ft (0.914 m) at any location within the intended footprint of the structure; and
c Where required by a state or locally adopted building code statute to include design for tsunami effects, Tsunami Risk Category II buildings with mean height above grade plane greater than the height designated in the statute and having inundation depth greater than 3 ft (0.914 m) at any location within the intended footprint of the structure.

EXCEPTION: Tsunami Risk Category II single-story buildings of any height without mezzanines or any occupiable roof level and not having any critical equipment or systems need not be designed for the tsunami loads and effects specified in this chapter.

For the purposes of this chapter, Tsunami Risk Category shall be as determined in accordance with Section 6.4.

Tsunami Design Zone shall be determined using the ASCE Tsunami Design Geodatabase of geocoded reference points shown in Figure 6.1-1. The ASCE Tsunami Design Geodatabase of geocoded reference points of runup and associated inundation limits of the Tsunami Design Zone is available at [http://asce7tsunami.online].

EXCEPTION: For coastal regions subject to tsunami inundation and not covered by Figure 6.1-1, Tsunami Design Zone, inundation limits, and runup elevations shall be determined using the site-specific procedures of Section 6.7, or for Tsunami Risk Category II or III structures, determined in accordance with the procedures of Section 6.5.1.1 using Figure 6.7-1.

Designated nonstructural components and systems associated with Tsunami Risk Category III Critical Facilities and Tsunami Risk Category IV structures subject to this chapter shall be located above, protected from, or otherwise designed for inundation in accordance with Section 6.15 so that they are able to provide their essential functions immediately following the Maximum Considered Tsunami event.

User Note: The ASCE Tsunami Design Geodatabase of geocoded reference points of runup and associated inundation limits of the Tsunami Design Zone is available at http://asce7tsunami.online. Sea level rise has not been incorporated into the Tsunami Design Zone maps, and any additive effect on the inundation at the site should be explicitly evaluated.

6.2 DEFINITIONS

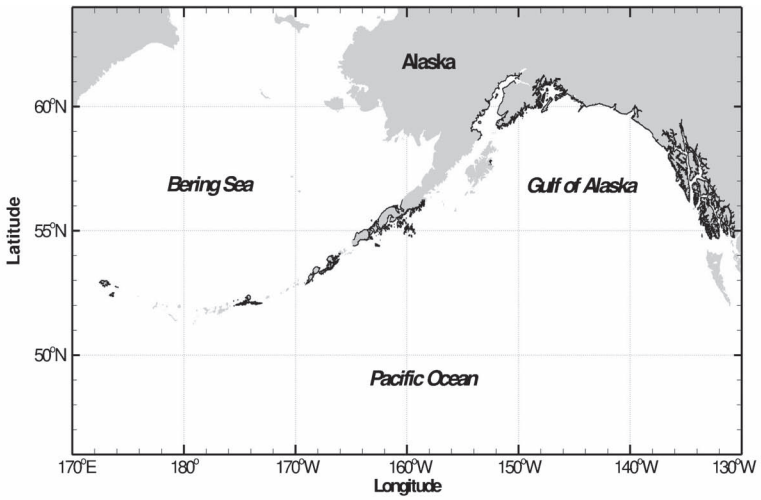
The following definitions apply only to the tsunami requirements of this chapter. Also see Figure 6.2-1 for an illustration of some key terms.

ASCE TSUNAMI DESIGN GEODATABASE: The ASCE database (version 2022-1.0) of geocoded reference points of Offshore 328 ft (100 m) depth Tsunami Amplitude, H_T, and Predominant Period, T_{TSU}, of the Maximum Considered Tsunami, disaggregated hazard source contribution figures, probabilistic subsidence, Runup Elevation and Inundation geocoded reference points, and Tsunami Design Zone maps.

BATHYMETRIC PROFILE: A cross section showing ocean depth plotted as a function of horizontal distance from a reference point (such as a coastline).

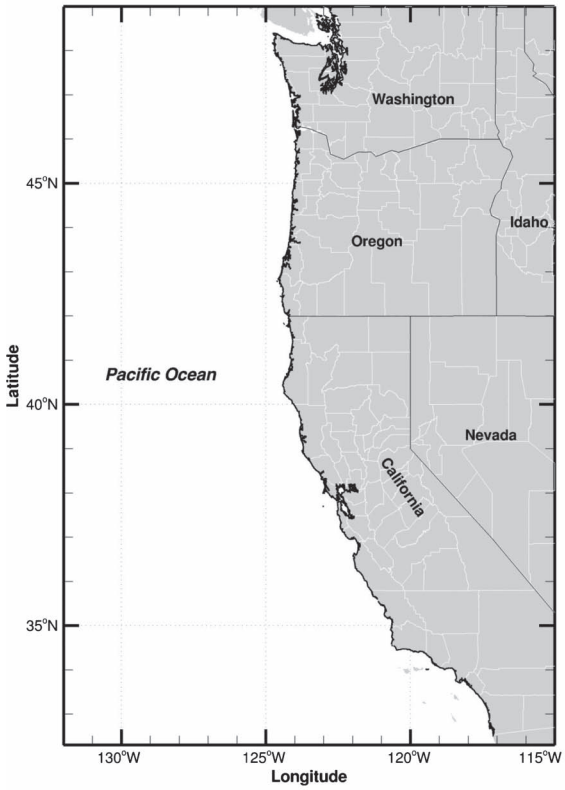
CHANNELIZED SCOUR: Scour that results from broad flow that is diverted to a focused area, such as return flow in a preexisting stream channel or alongside a seawall.

CLOSURE RATIO (of Inundated Projected Area): Ratio of the area of enclosure, not including glazing and openings, that is inundated to the total projected vertical plane area of the inundated enclosure surface exposed to flow pressure.



COLLAPSE PREVENTION STRUCTURAL PERFORMANCE LEVEL: A postevent damage state in which a structure has damaged components and continues to support gravity loads but retains little or no margin against collapse.

CRITICAL EQUIPMENT or CRITICAL SYSTEMS: Nonstructural components designated essential for the functionality of the Critical Facility or Essential Facility or that are necessary to maintain safe containment of hazardous materials.



CRITICAL FACILITY: Buildings and structures that provide services that are designated by federal, state, local, or tribal governments to be essential for the implementation of the response and recovery management plan or for the continued functioning of a community, such as facilities for power, fuel, water, communications, public health, major transportation infrastructure, and essential government operations. Critical Facilities comprise all public and private facilities deemed by a community to be essential for the delivery of vital services, protection of special populations, and the provision of other services of importance for that community.

DEADWEIGHT TONNAGE (DWT): Deadweight Tonnage (DWT) is a vessel's Displacement Tonnage (DT) minus its Lightship Weight (LWT). DWT is a classification used for the carrying capacity of a vessel that is equal to the sum of the weights of cargo, fuel, fresh water, ballast water, provisions, passengers, and crew; it does not include the weight of the vessel itself. Displacement Tonnage is the total weight of a fully loaded vessel. Lightship Weight is the weight of the vessel without cargo, crew, fuel, fresh water, ballast water, provisions, passengers, or crew.

(b) Pacific Coast

(c) Hawaii

Figure 6.1-1. Extent of ASCE Tsunami Design Geodatabase[1] of geocoded reference points of runup and associated inundation limits of the Tsunami Design Zone.[2][1]The ASCE Tsunami Design Geodatabase of geocoded reference points of runup and associated inundation limits of the Tsunami Design Zone is available at http://asce7tsunami.online.

[2]Sea level rise has not been incorporated into the Tsunami Design Zone maps, and any additive effect on the inundation at the site should be explicitly evaluated.

DESIGN STRENGTH: Nominal strength multiplied by a resistance factor, ϕ.

DESIGN TSUNAMI PARAMETERS: The tsunami parameters used for design, consisting of the inundation depths and flow velocities at the stages of inflow and outflow most critical to the structure and momentum flux.

DESIGNATED NONSTRUCTURAL COMPONENTS AND SYSTEMS: Nonstructural components and systems that

@seismicisolation

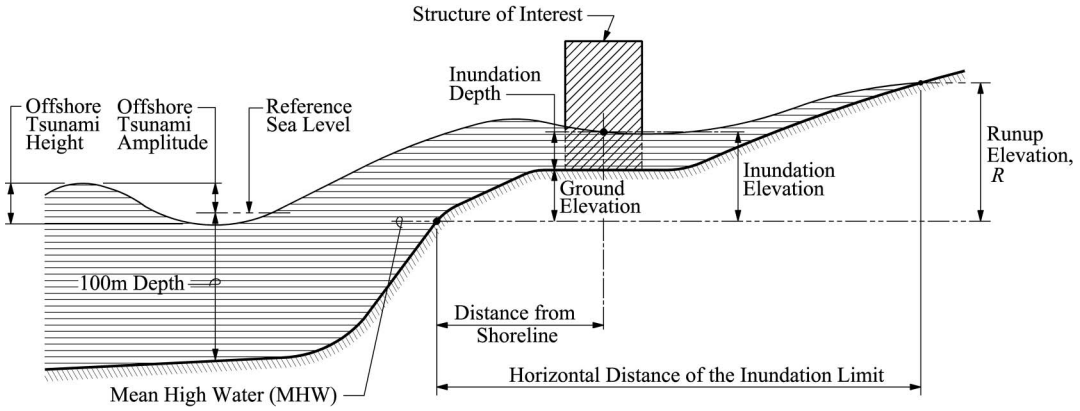

Figure 6.2-1. Illustration of key definitions along a flow transect in a tsunami design zone.

are assigned a component Importance Factor, I_p, equal to 1.5 per Section 13.1.3 of this standard.

DUCTILITY-GOVERNED ACTION: Any action on a structural component characterized by a postelastic force versus deformation curve that (1) has sufficient ductility and (2) results from an impulsive short-term force that is not sustained.

FORCE-SUSTAINED ACTIONS: Any action on a structural component characterized by a sustained force or a postelastic force versus deformation curve that is not ductility-governed due to lack of sufficient ductility.

FROUDE NUMBER, F_r: A dimensionless number defined by $u/\sqrt{(gh)}$, (where u is the flow velocity averaged over the cross section perpendicular to the flow), which is used to quantify the normalized tsunami flow velocity as a function of water depth.

GENERAL EROSION: A general wearing away and erosion of the land surface over a significant portion of the inundation area, excluding localized scour actions.

GRADE PLANE: A horizontal reference plane at the site representing the average elevation of finished ground level adjoining the structure at all exterior walls. Where the finished ground level slopes away from the exterior walls, the grade plane is established by the lowest points within the area between the structure and the property line or, where the property line is more than 6 ft (1.83 m) from the structure, between the structure and points 6 ft (1.83 m) from the structure.

HAZARD-CONSISTENT TSUNAMI SCENARIO: One or more surrogate tsunami scenarios generated from the principal disaggregated seismic source regions that replicate the Offshore Tsunami Amplitudes of the ASCE Tsunami Design Geodatabase or the offshore tsunami waveform characteristics of Figure 6.7-1 and Table 6.7-1 for the site of interest, taking into account the net effect of the probabilistic treatment of uncertainty into the offshore wave amplitude of the scenario(s).

HYDRODYNAMIC LOADS: Loads imposed on an object by water flowing against and around it.

HYDROSTATIC LOADS: Loads imposed on an object by a standing mass of water.

IMMEDIATE OCCUPANCY STRUCTURAL PERFORMANCE LEVEL: The postevent damage state in which a structure remains safe to occupy.

IMPACT LOADS: Loads that result from debris or other objects transported by the design tsunami striking a structure or portion thereof.

INUNDATION DEPTH: The depth of design tsunami water level, including relative sea level change, with respect to the grade plane at the structure.

INUNDATION ELEVATION: The elevation of the design tsunami water surface, including relative sea level change, with respect to vertical datum at Mean High Water (MHW).

INUNDATION LIMIT: The maximum horizontal inland extent of flooding for the Maximum Considered Tsunami, where the inundation depth above grade becomes zero; the horizontal distance that is flooded, relative to the shoreline defined where the elevation is at the Mean High Water (MHW).

LIFE SAFETY STRUCTURAL PERFORMANCE LEVEL: The postevent damage state is that in which a structure has damaged components but retains a margin against onset of partial or total collapse.

LIQUEFACTION SCOUR: The limiting case of pore pressure softening associated with hydrodynamic flow, where the effective stress drops to zero. In noncohesive soils, the shear stress required to initiate sediment transport also drops to zero during liquefaction scour.

LOCAL COSEISMIC TSUNAMI: A tsunami preceded by an earthquake with damaging effects felt within the subsequently inundated area.

LOCAL SCOUR: Removal of material from a localized portion of land surface, resulting from flow around, over, or under a structure or structural element.

MAXIMUM CONSIDERED TSUNAMI: A probabilistic tsunami having a 2% probability of being exceeded in a 50-year period or a 2,475-year mean recurrence interval.

MEAN HIGH WATER: The average of all the high water heights observed over the National Tidal Datum Epoch. For stations with shorter series, comparison of simultaneous observations with a control tide station is made in order to derive the equivalent datum of the National Tidal Datum Epoch.

MOMENTUM FLUX: The quantity $\rho_s hu^2$ for a unit width based on the depth-averaged flow speed, u, over the inundation depth, h, for equivalent fluid density, ρ_s, having the units of force per unit width.

NEARSHORE PROFILE: Cross-sectional bathymetric profile from the shoreline to a water depth of 328 ft (100 m).

NEARSHORE TSUNAMI AMPLITUDE: The Maximum Considered Tsunami amplitude immediately off the coastline at 33 ft (10 m) of water depth.

NONBUILDING CRITICAL FACILITY STRUCTURE: Nonbuilding structure whose Tsunami Risk Category is designated as either III or IV.

NONBUILDING STRUCTURE: A structure other than a building.

@seismicisolation
@seismicisolation

OFFSHORE TSUNAMI AMPLITUDE: Maximum Considered Tsunami amplitude relative to the Reference Sea Level, measured where the undisturbed water depth is 328 ft (100 m).

OFFSHORE TSUNAMI HEIGHT: Waveform vertical dimension of the Maximum Considered Tsunami from consecutive trough to crest, measured where the undisturbed water depth is 328 ft (100 m), after removing the tidal variation.

OPEN STRUCTURE: A structure in which the portion within the inundation depth has no greater than 20% closure ratio, and in which the closure does not include any Tsunami Breakaway Walls, and which does not have interior partitions or contents that are prevented from passing through and exiting the structure as unimpeded waterborne debris.

PILE: A deep foundation element, which includes piers, caissons, and piles.

PILE SCOUR: A special case of enhanced local scour that occurs at a pile, bridge pier, or similar slender structure.

PLUNGING SCOUR: A special case of enhanced local scour that occurs when the flow passes over a complete or nearly complete obstruction, such as a barrier wall, and drops steeply onto the ground below, scouring out a depression.

PORE PRESSURE SOFTENING: A mechanism that enhances scour through increased pore-water pressure generated within the ground during rapid tsunami loading and the release of that pressure during drawdown.

PORE PRESSURE SOFTENING PARAMETER, Λ_T: A dimensionless parameter defined by Equation (6.12-1) characterizing the fraction of the weight of soil grains supported by tsunami-induced excess pore water pressure.

PRIMARY STRUCTURAL COMPONENT: Structural components required to resist tsunami forces and actions and inundated structural components of the gravity-load-carrying system.

RECOGNIZED LITERATURE: Published research findings and technical papers that are approved by the Authority Having Jurisdiction.

REFERENCE SEA LEVEL: The sea level datum used in site-specific inundation modeling that is typically taken to be Mean High Water (MHW).

RELATIVE SEA LEVEL CHANGE: The local change in the level of the ocean relative to the land, which might be caused by ocean rise and/or subsidence of the land.

RUNUP ELEVATION: Ground elevation at the maximum tsunami inundation limit, including relative sea level change, with respect to the Mean High Water (MHW) datum.

SECONDARY STRUCTURAL COMPONENT: A structural component that is not primary.

SHOALING: The increase in wave height and wave steepness caused by the decrease in water depth as a wave travels into shallower water.

SOLITON FISSION: Short-period waves generated on the front edge of a tsunami waveform under conditions of shoaling on a long and gentle seabed slope or having abrupt seabed discontinuities, such as fringing reefs.

STRUCTURAL COMPONENT: A component of a building that provides gravity-load-carrying or lateral-force resistance as part of a continuous load path to foundation, including beams, columns, slabs, braces, walls, wall piers, coupling beams, and connections.

STRUCTURAL WALL: A wall that provides gravity-load-carrying support or one that is designed to provide lateral-force resistance.

SURGE: Rapidly rising water level resulting in horizontal flow inland.

SUSCEPTIBLE DEPTH, D_e: The depth of soil susceptible to pore pressure softening.

SUSTAINED FLOW SCOUR: Enhanced local scour that results from flow acceleration around a structure. The flow acceleration and associated vortices increase the bottom shear stress and scour out a localized depression.

TOE SCOUR: A special case of enhanced local scour that occurs at the base of a seawall or similar structure on the side directly exposed to the flow. Toe scour can occur whether or not the structure is overtopped.

TOPOGRAPHIC TRANSECT: Profile of vertical elevation data versus horizontal distance along a cross section of the terrain, in which the orientation of the cross section is perpendicular or at some specified orientation angle to the shoreline.

TSUNAMI: A series of waves with variable long periods, typically resulting from earthquake-induced uplift or subsidence of the seafloor.

TSUNAMI AMPLITUDE: The absolute value of the difference between a particular peak or trough of the tsunami and the undisturbed sea level at the time.

TSUNAMI BORE: A steep and turbulent broken wavefront generated on the front edge of a long-period tsunami waveform when shoaling over mild seabed slopes or abrupt seabed discontinuities such as fringing reefs, or in a river estuary, per Section 6.6.4. Soliton fission in the Nearshore Profile can often lead to the occurrence of tsunami bores.

TSUNAMI BORE HEIGHT: The height of a broken tsunami surge above the water level in front of the bore, or above the grade elevation if the bore arrives on nominally dry land.

TSUNAMI BREAKAWAY WALL: Any type of wall subject to flooding that is not required to provide structural support to a building or other structure and that is designed and constructed such that, before the development of the design flow conditions of inundation Load Case 1, as defined in Section 6.8.3.1, the wall will collapse or detach in such a way that (1) it allows substantially free passage of floodwaters and external or internal waterborne debris, including unattached building contents, and (2) it does not damage the structure or supporting foundation system.

TSUNAMI DESIGN ZONE: An area identified on the Tsunami Design Zone Map between the shoreline and the inundation limit, within which structures are analyzed and designed for inundation by the Maximum Considered Tsunami.

TSUNAMI DESIGN ZONE MAP: The map given in Figure 6.1-1 designating the potential horizontal inundation limit of the Maximum Considered Tsunami, or a state or local jurisdiction's probabilistic map produced in accordance with Section 6.7 of this chapter.

TSUNAMI EVACUATION MAP: An evacuation map based on a tsunami inundation map based on assumed scenarios that is developed and provided to a community by either the applicable state agency or NOAA under the National Tsunami Hazard Mitigation Program. Tsunami inundation maps for evacuation may be significantly different in extent than the Probabilistic Tsunami Design Zone, and Tsunami Evacuation Maps are not intended for design or land use purposes.

TSUNAMI-PRONE REGION: The coastal region in the United States addressed by this chapter with quantified probability in the recognized literature of tsunami inundation hazard with runup greater than 3 ft (0.914 m) caused by tsunamigenic earthquakes in accordance with the Probabilistic Tsunami Hazard Analysis method given in this chapter.

TSUNAMI RISK CATEGORY: The Risk Category from Section 1.5, as modified for specific use related to this chapter per Section 6.4.

@seismicisolation

TSUNAMI VERTICAL EVACUATION REFUGE STRUCTURE: A structure designated and designed to serve as a point of refuge to which a portion of the community's population can evacuate above a tsunami when high ground is not available.

6.3 SYMBOLS AND NOTATION

A_{beam} = Vertical projected area of an individual beam element
A_{col} = Vertical projected area of an individual column element
A_d = Vertical projected area of obstructing debris accumulated on structure
A_{wall} = Vertical projected area of an individual wall element
a_1 = Amplitude of the leading pulse (negative for a leading depression tsunami)
a_2 = Amplitude of the following, or second, pulse
B = Overall building width
b = Width subject to force
C_{bs} = Force coefficient with breakaway slab
C_{cx} = Proportion of closure coefficient
C_d = Drag coefficient based on quasi-steady forces
C_{dis} = Discharge coefficient for overtopping
C_o = Orientation coefficient (of debris)
c_v = Coefficient of consolidation
c_{2V} = Plunging scour coefficient
D = Dead load
D_a = Diameter of rock armor
D_s = Scour depth
d_d = Additional drop in grade to the base of wall on the side of a seawall or freestanding retaining wall subject to plunging scour
DT = Displacement Tonnage
DWT = Deadweight Tonnage of vessel
E = Earthquake load
E_g = Hydraulic head in the Energy Grade Line Analysis
E_{mh} = Horizontal Seismic Load Effect, including overstrength factor, defined in Section 12.4.3.1
F_d = Drag force on an element or component
F_{dx} = Drag force on the building or structure at each level
F_h = Unbalanced hydrostatic lateral force
F_i = Debris impact design force
F_{ni} = Nominal maximum instantaneous debris impact force
F_{pw} = Hydrodynamic force on a perforated wall
F_r = Froude number $= u/\sqrt{gh}$
F_{TSU} = Tsunami load or effect
F_v = Buoyancy force
F_w = Load on wall or pier
$F_{w\theta}$ = Force on a wall oriented at an angle θ to the flow
F_Λ = Pore pressure softening vertical flux index
f_{uw} = Equivalent uniform lateral force per unit width
g = Acceleration caused by gravity
H_B = Barrier height of a levee, seawall, or freestanding retaining wall
H_O = Depth to which a barrier is overtopped above the barrier height
H_T = Offshore Tsunami Amplitude determined from Figure 6.7-1
H_{TSU} = Load caused by tsunami-induced lateral earth pressure under submerged conditions
h = Tsunami inundation depth above grade plane at the structure
h_{draw} = Difference between the maximum inundation depth, h_{max}, and the residual water level after drawdown of the associated wave
h_e = Inundated height of an individual element
h_i = Inundation depth at point i
h_{max} = Maximum inundation depth above grade plane at the structure
h_o = Offshore water depth
h_r = Residual water height within a building
h_s = Height of structural floor slab above grade plane at the structure
h_{ss} = Height of the bottom of the structural floor slab, taken above grade plane at the structure
h_{sx} = Story height of story x
h_w = Height of wall
I_{tsu} = Importance Factor for tsunami forces to account for additional uncertainty in estimated parameters
I_Λ = Pore pressure softening drawdown inertia index
k = Effective stiffness of the impacting debris or the lateral stiffness of the impacted structural element
k_s = Fluid density factor to account for suspended soil and other smaller flow-embedded objects that are not considered in Section 6.11
L = Live load
L_{refuge} = Public assembly live load effect in the tsunami refuge floor area
l_w = Length of a structural wall
LWT = Lightship Weight of vessel
m = Component demand modification factor accounting for expected ductility, applied to the expected strength of a ductility-governed element action, to obtain the acceptable structural component capacity at a particular performance level when using a linear static analysis procedure
$m_{contents}$ = Mass of contents in a shipping container
m_d = Mass of debris object
MCT = Maximum Considered Tsunami
n = Manning's coefficient
P_u = Uplift pressure on slab or building horizontal element
P_{ur} = Reduced uplift pressure for slab with opening
Q_{CE} = Expected strength of the structural element
Q_{CS} = Specified strength of the structural element
Q_{UD} = Ductility-governed force caused by gravity and tsunami loading
Q_{UF} = Maximum force generated in the element caused by gravity and tsunami loading
q = Discharge per unit width over an overtopped structure
R = Mapped tsunami runup elevation
R_{max} = Dynamic response ratio
R_s = Net upward resistance from foundation elements
S = Snow load
s = Friction slope of the energy grade line
t = Time
t_d = Duration of debris impact
t_o = Offset time of the wave train
T_{draw} = Site-specific drawdown time, that is, the time from the peak of the transformed onshore waveform to the following trough
T_{TSU} = Predominant wave period, or the time from the start of the first pulse to the end of the second pulse at the 328 ft (100 m) bathymetric depth
U = Jet velocity of plunging flow
u = Tsunami flow velocity
u_{max} = Maximum tsunami flow velocity at the structure
u_v = Vertical component of tsunami flow velocity
V_w = Displaced water volume
W_d = Weight of debris
W_s = Weight of the structure

@seismicisolation

w_g = Width of opening gap in slab
x = Horizontal distance inland from the Mean High Water (MHW) shoreline
x_R = Mapped inundation limit distance inland from the Mean High Water (MHW) shoreline
z = Ground elevation above the Mean High Water (MHW) datum
α = Froude number coefficient in the Energy Grade Line Analysis
β = Effective wake angle downstream of an obstructing structure to the structure of interest
γ_b = Buoyant weight density of soil
γ_s = Minimum fluid weight density for design hydrostatic loads
γ_{sw} = Effective weight density of seawater
Δx_i = Incremental distance used in the Energy Grade Line Analysis
ξ_{100} = Surf similarity parameter using 328 ft (100 m) nearshore wave characteristics
η = Free surface elevation as a function of time, t, used to drive the offshore boundary condition at the 328 ft (100 m) depth contour
κ_d = Drainage factor
θ = Angle between the longitudinal axis of a wall and the flow direction
ϕ = Structural resistance factor
ρ_s = Minimum fluid mass density for design hydrodynamic loads
ρ_{sw} = Effective mass density of seawater
ϕ = Average slope of grade at the structure
ϕ_i = Average slope of grade at point i
$\phi_{i,\ 200}$ = Topographic slope averaged over a distance of 200 ft (60.96 m) along a transect
Λ_T = Pore pressure softening parameter
Ω = Angular frequency of the waveform, equal to $2\pi/T$, where T is the wave period
Ω_O = Overstrength factor for the lateral-force-resisting system given in Table 12.2-1
Φ = Mean slope angle of the Nearshore Profile
ψ = Angle between the plunging jet at the scour hole and the horizontal

6.4 TSUNAMI RISK CATEGORIES

For the purposes of this chapter, tsunami risk categories for buildings and other structures shall be the risk categories given in Section 1.5 with the following modifications:

1. Federal, state, local, or tribal governments shall be permitted to include Critical Facilities in Tsunami Risk Category III, such as power-generating stations, water-treatment facilities for potable water, wastewater-treatment facilities, and other public utility facilities not included in Risk Category IV.
2. The following structures need not be included in Tsunami Risk Category IV, and state, local, or tribal governments shall be permitted to designate them as Tsunami Risk Category II or III:
   (a) Fire stations, ambulance facilities, and emergency vehicle garages;
   (b) Earthquake or hurricane shelters;
   (c) Emergency aircraft hangars; and
   (d) Police stations that do not have holding cells and that are not uniquely required for postdisaster emergency response as a Critical Facility.
3. Tsunami Vertical Evacuation Refuge Structures shall be included in Tsunami Risk Category IV.

6.5 ANALYSIS OF DESIGN INUNDATION DEPTH AND FLOW VELOCITY

6.5.1 Tsunami Risk Category II and III Buildings and Other Structures The Maximum Considered Tsunami inundation depth and tsunami flow velocity characteristics at a Tsunami Risk Category II or III building or other structure shall be determined by using the Energy Grade Line Analysis of Section 6.6 and the inundation limit and runup elevation of the Maximum Considered Tsunami given in Figure 6.1-1.

The site-specific Probabilistic Tsunami Hazard Analysis (PTHA) in Section 6.7 shall be permitted as an alternate to the Energy Grade Line Analysis. Site-specific velocities determined by PTHA shall be subject to the limitation in Section 6.7.6.8.

EXCEPTION: For Tsunami-Prone Regions not covered by Figure 6.1-1, the procedures of Section 6.5.1.1 shall apply to Tsunami Risk Category II and III buildings and other structures.

6.5.1.1. Runup Evaluation for Areas Where No Map Values Are Given For Tsunami Risk Category II and III buildings and other structures where no mapped inundation limit is shown in Figure 6.1-1, the ratio of tsunami runup elevation above Mean High Water Level to Offshore Tsunami Amplitude, R/H_T, shall be permitted to be determined using the surf similarity parameter ξ_{100}, according to Equation (6.5-2a, b, c, d, or e) and Figure 6.5-1.

The surf similarity parameter, ξ_{100}, for this application to tsunami engineering shall be determined in accordance with Equation (6.5-1).

$$\xi_{100} = \frac{T_{\text{TSU}}}{\cot\Phi}\sqrt{\frac{g}{2\pi H_T}} \tag{6.5-1}$$

where Φ is the mean slope angle of the Nearshore Profile taken from the 328 ft (100 m) water depth to the Mean High Water elevation along the axis of the topographic transect for the site. H_T is the Offshore Tsunami Amplitude, and T_{TSU} is the wave period of the tsunami at 328 ft (100 m) water depth. H_T and T_{TSU} are given in Figure 6.7-1.

$$\text{For} \quad \xi_{100} \le 0.6,\ R/H_T = 1.5 \tag{6.5-2a}$$

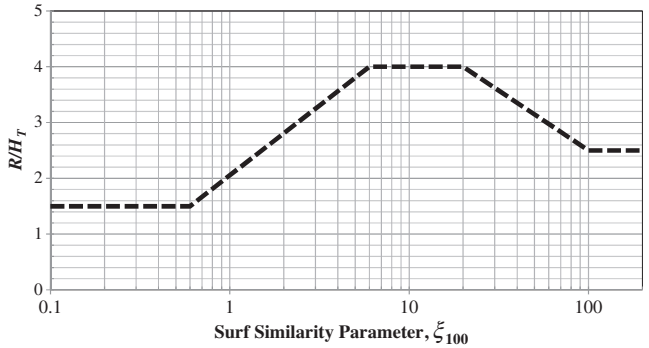

Figure 6.5-1. Runup ratio, R/H_T, as a function of the mean slope of the surf similarity parameter, ξ_{100}, where no mapped inundation limit exists.

@seismicisolation

$$\text{For} \quad \xi_{100} > 0.6 \text{ and } \xi_{100} \le 6, \quad R/H_T = 2.50[\log_{10}(\xi_{100})] + 2.05 \tag{6.5-2b}$$

$$\text{For} \quad \xi_{100} > 6 \text{ and } \xi_{100} \le 20, \; R/H_T = 4.0 \tag{6.5-2c}$$

$$\text{For} \quad \xi_{100} > 20 \text{ and } \xi_{100} \le 100, \quad R/H_T = -2.15[\log_{10}(\xi_{100})] + 6.80 \tag{6.5-2d}$$

$$\text{For} \quad \xi_{100} > 100, \; R/H_T = 2.5 \tag{6.5-2e}$$

EXCEPTION: These equations shall not be used where there is an expectation of wave focusing such as at headlands, in V-shaped bays, or where the on-land flow fields are expected to vary significantly in the direction parallel to the shoreline because of longshore variability of topography.

6.5.2 Tsunami Risk Category IV Buildings and Other Structures The Energy Grade Line Analysis of Section 6.6 shall be performed for Tsunami Risk Category IV buildings and other structures, and the site-specific Probabilistic Tsunami Hazard Analysis (PTHA) of Section 6.7 shall also be performed. Site-specific velocities determined by site-specific PTHA determined to be less than the Energy Grade Line Analysis shall be subject to the limitation in Section 6.7.6.8. Site-specific velocities determined to be greater than the Energy Grade Line Analysis shall be used.

EXCEPTION: For structures other than Tsunami Vertical Evacuation Refuge Structures, a site-specific Probabilistic Tsunami Hazard Analysis need not be performed where the inundation depth resulting from the Energy Grade Line Analysis is determined to be less than 12 ft (3.66 m) at any point within the location of the Tsunami Risk Category IV structure.

6.5.3 Sea Level Change The direct physical effects of potential relative sea level change shall be considered in determining the maximum inundation depth during the project lifecycle. A project lifecycle of not less than 50 years shall be used. The minimum rate of potential relative sea level change shall be the historically recorded sea level change rate for the site. The potential increase in relative sea level during the project lifecycle of the structure shall be added to the tsunami runup elevations.

6.6 INUNDATION DEPTHS AND FLOW VELOCITIES BASED ON RUNUP

6.6.1 Maximum Inundation Depth and Flow Velocities Based on Runup The maximum inundation depths and flow velocities associated with the stages of tsunami flooding shall be determined in accordance with Section 6.6.2. Calculated flow velocity shall not be taken as less than 10 ft/s (3.0 m/s) and need not be taken as greater than the lesser of $1.5(gh_{\max})^{1/2}$ and 50 ft/s (15.2 m/s).

Where the maximum topographic elevation along the topographic transect between the shoreline and the inundation limit is greater than the runup elevation, one of the following methods shall be used.

1. The site-specific procedure of Section 6.7.6 shall be used to determine inundation depth and flow velocities at the site, subject to the range of calculated velocities defined in the first paragraph of this section.
2. For determination of the inundation depth and flow velocity at the site, the procedure of Section 6.6.2, Energy Grade Line Analysis, shall be used, assuming a runup elevation and horizontal inundation limit that has at least 100% of the maximum topographic elevation along the topographic transect.
3. Where the site lies within a completely overwashed area for which Inundation Depth Points are provided in the ASCE Tsunami Design Geodatabase, the inundation elevation profiles shall be determined using the Energy Grade Line Analysis with the following modifications.
   (a) The Energy Grade Line Analysis shall be initiated from the inland edge of the overwashed land with an inundation elevation equal to the maximum topographic elevation of the overwashed portion of the transect.
   (b) The Froude number shall be 1 at the inland edge of the overwashed land and shall vary linearly with distance to match the value of the Froude number determined at the shoreline per the coefficient α.
   (c) The Energy Grade Line Analysis flow elevation profile shall be uniformly adjusted with a vertical offset such that the computed inundation depth at the Inundation Depth Point is at least the depth specified by the ASCE Tsunami Design Geodatabase, but the flow elevation profile shall not be adjusted lower than the topographic elevations of the overwashed land transect.

6.6.2 Energy Grade Line Analysis of Maximum Inundation Depths and Flow Velocities The maximum velocity and maximum inundation depth along the ground elevation profile up to the inundation limit shall be determined using the Energy Grade Line Analysis. The orientations of the topographic transect profiles used shall be determined considering the requirements of Section 6.8.6.1. The ground elevation along the transect, z_i, shall be represented as a series of linear sloped segments each with a Manning's coefficient consistent with the equivalent terrain macroroughness friction of that terrain segment. The Energy Grade Line Analysis shall be performed incrementally in accordance with Equation (6.6-1) across the topographic transect in a stepwise procedure. Equation (6.6-1) shall be applied across the topographic transect from the runup where the hydraulic head at the inundation limit, x_R, is zero, and the water elevation is equal to the runup, R, by calculating the change in hydraulic head at each increment of terrain segment toward the shoreline until the site of interest is reached, as shown in Figure 6.6-1.

$$E_{g,i} = E_{g,i-1} + (\varphi_i + s_i)\Delta x_i \tag{6.6-1}$$

where

$E_{g,i}$ = Hydraulic head at point $i = h_i + u_i^2/2g = h_i(1 + 0.5F_{ri}^2)$;
h_i = Inundation depth at point i;
u_i = Maximum flow velocity at point i;
φ_i = Average ground slope between points i and $i-1$;
F_{ri} = Froude number $= u/(gh)^{1/2}$ at point i;
Δx_i = Increment of horizontal distance $(x_{i-1} - x_i)$ distance, which shall not be coarser than 100 ft (30.5 m) spacing;
x_i = Horizontal distance inland from the Mean High Water (MHW) shoreline at point i; and
s_i = Friction slope of the energy grade line between points i and $i-1$, is calculated per Equation (6.6-2).

$$s_i = (u_i)^2/((1.49/n)^2 h_i^{4/3}) = gF_{ri}^2/((1.49/n)^2 h_i^{1/3}) \tag{6.6-2}$$

$$s_i = (u_i)^2/((1.00/n)^2 h_i^{4/3}) = gF_{ri}^2/((1.00/n)^2 h_i^{1/3}) \tag{6.6-2.SI}$$

@seismicisolation

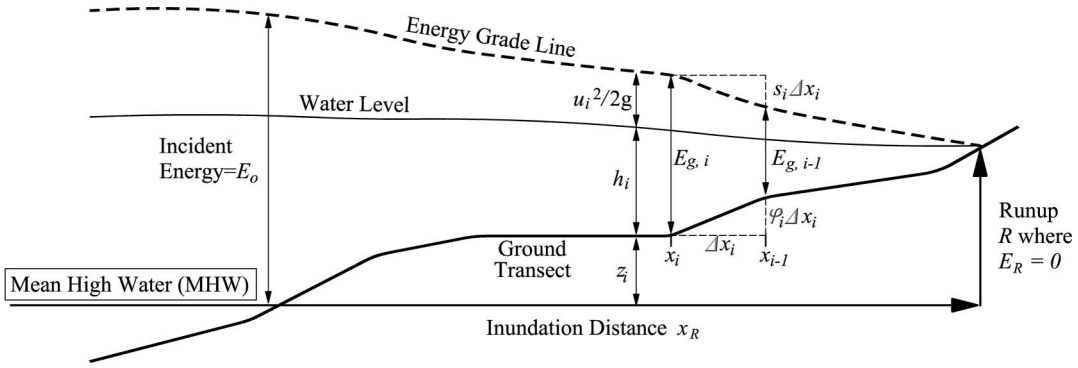

Figure 6.6-1. Energy method for overland tsunami inundation depth and velocity.

Note: ***R*** is the design tsunami runup elevation above MHW datum; $\boldsymbol{x_R}$ is the design inundation distance inland from MHW shoreline; and $\boldsymbol{z_i}$ is the ground elevation above MHW datum at point ***i***.

Table 6.6-1. Manning's Roughness, *n*, for Energy Grade Line Analysis.

Description of Frictional Surface	*n*
Coastal water nearshore bottom friction	0.025 to 0.03
Open land or field	0.025
All other cases	0.03
Buildings of at least urban density	0.04

where n is Manning's coefficient of the terrain segment being analyzed, according to Table 6.6-1, and E_R is the hydraulic head of zero at the point of runup.

Velocity shall be determined as a function of inundation depth, in accordance with the prescribed value of the Froude number calculated according to Equation (6.6-3).

$$F_r = \alpha\left(1 - \frac{x}{x_R}\right)^{0.5} \tag{6.6-3}$$

where a value of 1.0 shall be used for α, the Froude number coefficient. Where tsunami bores are required to be considered per Section 6.6.4, the tsunami bore conditions specified in Sections 6.10.2.3 and 6.10.3.3 shall be applied using the values of h_e and $(h_e u^2)_{bore}$ evaluated with $\alpha = 1.3$.

At locations along the topographic transect where the average slope, $\varphi_{i,\,200}$, is negative, the velocity determined in accordance with Equation (6.6-3) shall be increased by an amount Δu_i per Equation (6.6-4), which need not be taken greater than 6 ft/s (1.83 m/s).

$$\Delta u_i = u_i \left|(\varphi_{i,200})\right|^{0.25} \tag{6.6-4}$$

where $\varphi_{i,\,200}$ is the slope averaged over a distance of 200 ft (60.96 m) centered on the transect point, x_i.

As a final step in the analysis, apply the minimum flow velocity required by Section 6.6.1 where necessary. The resulting values at the site are used as the maximum inundation depth, h_{max}, and the maximum velocity, u_{max}.

6.6.3 Terrain Roughness It shall be permitted to perform inundation analysis assuming bare-earth conditions with equivalent macroroughness. Bed roughness shall be prescribed using the Manning's coefficient n. It shall be permitted to use the values listed in Table 6.6-1 or other values based on terrain analysis in the recognized literature or as specifically validated for the inundation model used.

6.6.4 Tsunami Bores Tsunami bores shall be considered where any of the following conditions exist:

1. The prevailing nearshore bathymetric slope is 1/100 or milder,
2. Shallow fringing reefs or other similar step discontinuities in nearshore bathymetric slope occur,
3. Where historically documented,
4. As described in the recognized literature, or
5. As determined by a site-specific inundation analysis.

Where tsunami bores are deemed to occur, the tsunami bore conditions specified in Sections 6.10.2.3 and 6.10.3.3 shall be applied.

6.6.5 Amplified Flow Velocities Flow velocities determined in this section shall be adjusted for flow amplification in accordance with Section 6.8.5 as applicable. The adjusted value need not exceed the maximum limit specified in Section 6.6.1.

6.7 INUNDATION DEPTHS AND FLOW VELOCITIES BASED ON SITE-SPECIFIC PROBABILISTIC TSUNAMI HAZARD ANALYSIS

When required by Section 6.5, the inundation depths and flow velocities shall be determined by site-specific inundation studies complying with the requirements of this section. Site-specific analyses shall use the ASCE Tsunami Design Geodatabase of geocoded reference points of Offshore Tsunami Amplitude and dominant waveform period shown in Figure 6.7-1 as input to an inundation numerical model or shall use an integrated generation, propagation, and inundation model that replicates the given offshore tsunami waveform amplitude and period from the seismic sources given in Section 6.7.1. The ASCE Tsunami Design Geodatabase of geocoded reference points of offshore 328 ft (100 m) depth, Tsunami Amplitude, H_T, and predominant period, T_{TSU}, of the Maximum Considered Tsunami is available at http://asce7tsunami.online.

6.7.1 Tsunami Waveform The tsunami waveform used along the offshore boundary of 328 ft (100 m) bathymetry shall be constructed in accordance with Equation (6.7-1), as illustrated in Figure 6.7-2.

@seismicisolation

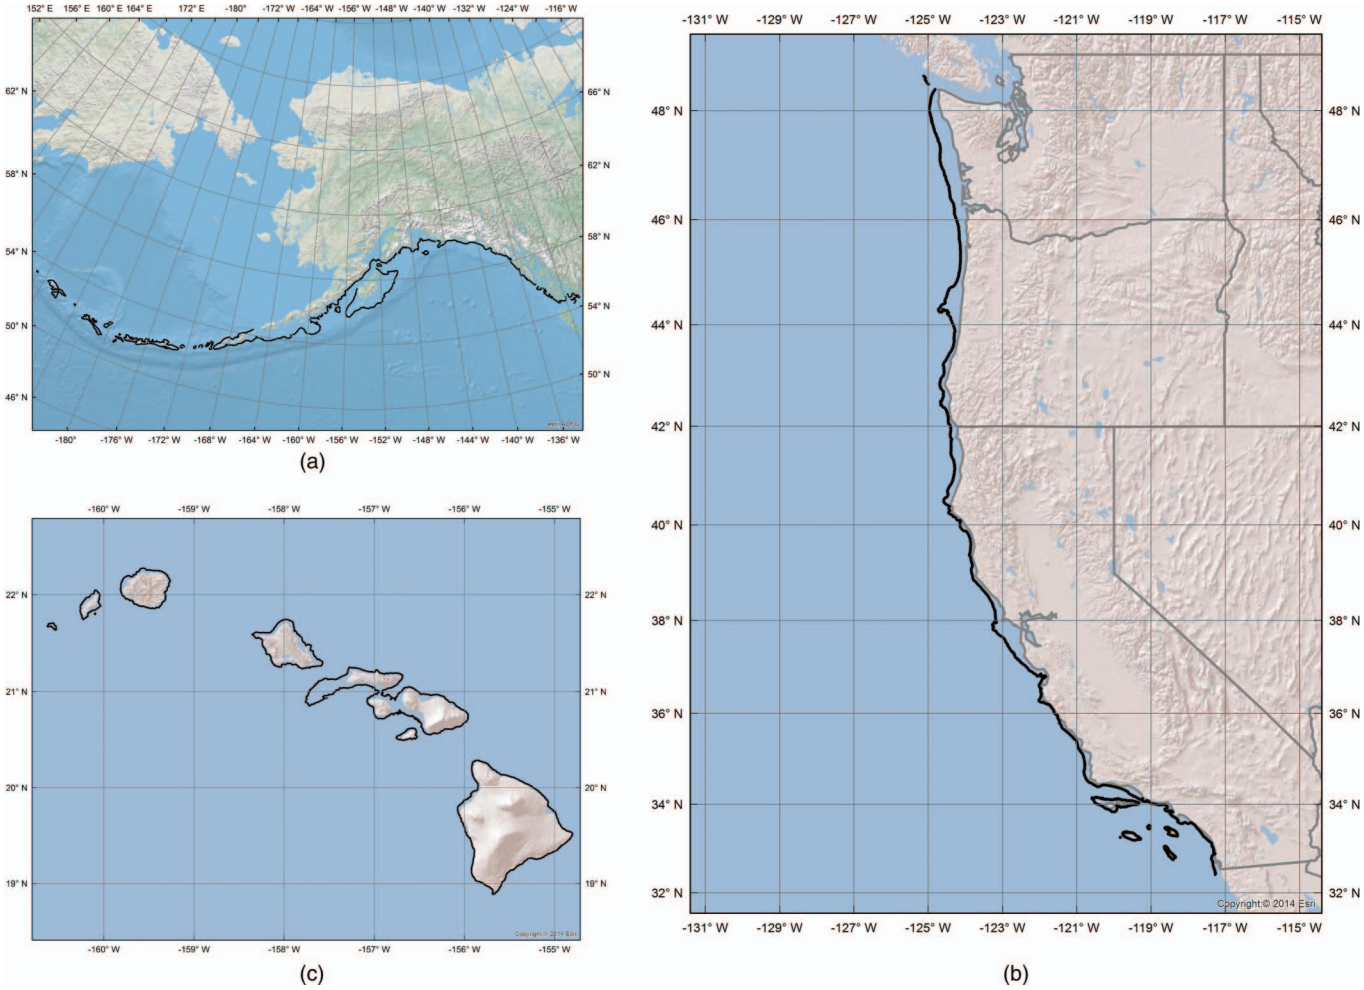

Figure 6.7-1. Extent of ASCE Tsunami Design Geodatabase of geocoded reference points of Offshore Tsunami Amplitude, H_T[at 328 ft (100 m) depth], and predominant period, T_{TSU}, of the Maximum Considered Tsunami.

Note: The ASCE Tsunami Design Geodatabase of geocoded points of Offshore Tsunami Amplitude, H_T,[at 328 ft (100 m)] depth, and predominant period, T_{TSU}, of the Maximum Considered Tsunami is available at http://asce7tsunami.online.

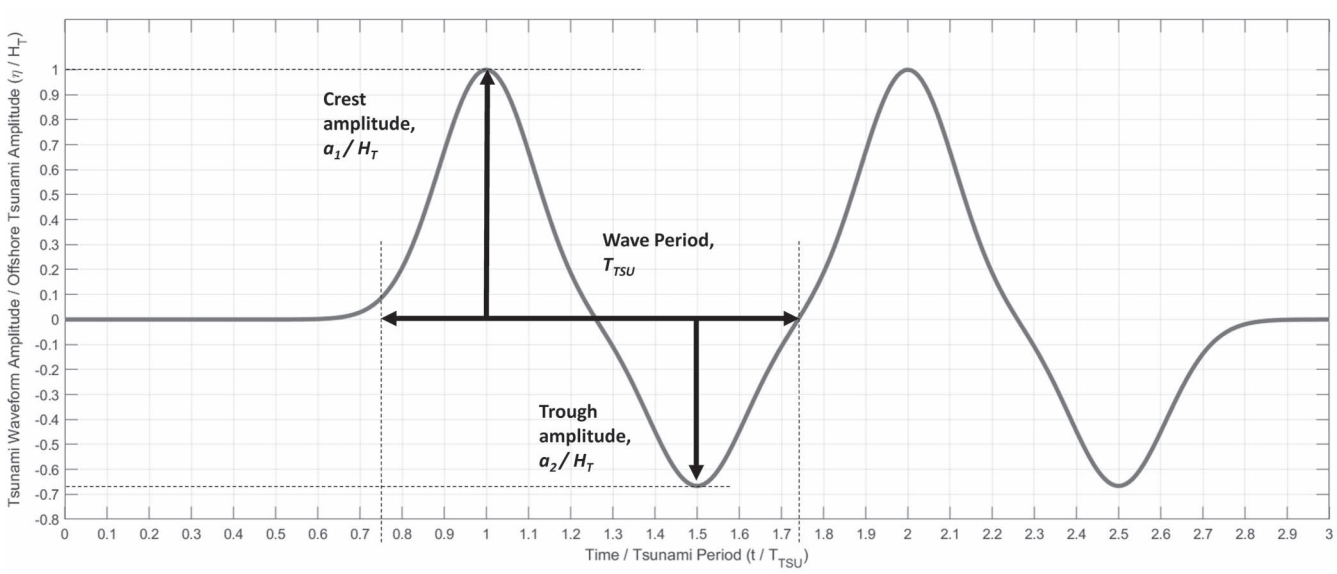

Figure 6.7-2. Illustration of tsunami offshore incident waveform parameters at 328 ft (100 m) depth with $N = 2$.

@seismicisolation

$$\eta = \sum_{i=1}^{N} [a_1 e^{-\{\omega[t-t_o-(i-1)T_{TSU}]\}^2} + a_2 e^{-\{\omega[t-t_o-(i-0.5)T_{TSU}]\}^2}] \quad (6.7\text{-}1)$$

where the total wave height of the waveform is $abs(a_1) + abs(a_2)$, and

η = Free surface elevation (ft or m) as a function of time, t, used to drive the offshore boundary condition at the 328 ft (100 m) depth contour;
N = Number of individual waves (peak and trough pairs) to be included in the tsunami waveform;
a_1 = Amplitude of the leading pulse (in ft or m)—it is negative for a leading depression tsunami;
a_2 = Amplitude of the following, or second, pulse (in ft or m);
T_{TSU} = Wave period, or the time from the start of the first pulse to the end of the second pulse;
ω = Angular frequency of the waveform, equal to $2\pi/T_{TSU}$; and
t_o = Offset time of the wave train, generally set equal to T_{TSU}.

The possibility of negative and positive leading amplitudes of the tsunami shall be considered, with the waveform given by Equation (6.7-1) using the values of parameters given by the ASCE Tsunami Design Geodatabase of geocoded reference points shown in Figure 6.7-1. For an inundation numerical model, the values given in Table 6.7-1 shall also be used to define at least two possible waveforms using the minimum and maximum prescribed values of a_2. An integrated generation, propagation, and inundation model that replicates the given offshore tsunami waveform amplitude and period from the seismic sources need not use the values given in Table 6.7-1.

6.7.2 Tsunamigenic Sources Tsunami sources shall consider the following to the extent that probabilistic hazards are documented in the recognized literature:

1. Local and distant subduction zone sources. It shall be permitted to use a system of delineated and discretized subduction zones in the Pacific basin composed of systems of rectangular subfaults and their corresponding tectonic parameters.
   (a) Principal seismic sources shall include but are not restricted to Alaska: (Alaska-Aleutian, Kamchatka-Kurile), California: (Alaska-Aleutian, Cascadia, Kamchatka-Kuril, Chile-Peru), Hawaii: (Alaska-Aleutian, Chile-Peru, Kamchatka-Kuril, Japan, Izu-Bonin-Mariana Islands), and Oregon and Washington: (Cascadia, Alaska, Kamchatka-Kuril).
   (b) The maximum moment magnitude considered in the probability distribution of seismicity shall include the values given in Table 6.7-2.
2. Local, non-subduction-zone seismic fault sources capable of moment magnitude of 7 or greater, including offshore and/or submarine fault sources that are tsunamigenic.
3. Local coastal and submarine landslide sources documented in the recognized literature as being tsunamigenic of similar runup, as determined by historical evidence or having estimated probabilities within an order of magnitude of the principal seismic fault sources.

Table 6.7-2. Maximum Moment Magnitude.

Subduction Zone	Maximum Moment Magnitude, M_w
Alaska-Aleutian	9.5
Cascadia	9.2
Chile-Peru	9.5
Izu-Bonin-Marianas	9.0
Kamchatka-Kurile and Japan Trench	9.4

6.7.3 Earthquake Rupture Unit Source Tsunami Functions for Offshore Tsunami Amplitude The tsunami modeling algorithm shall be based on earthquake rupture slip distributions for tsunami events, which shall be permitted to be represented by a linear combination of unit source functions using a precomputed database of tsunami Green's source functions.

1. Tsunami waveform generation shall be permitted to be modeled by deconstructing a tsunami that is generated by an earthquake into a sum of individual tsunami waveforms composed from a scaled set of unit source subfaults that describe the earthquake rupture in terms of location, orientation, and rupture direction and sequence.
2. The waveforms defining the time series of wave height and velocity from a unit slip on each subfault shall be weighted by the actual slip or rupture distribution for the event and then summed linearly.
3. The algorithm shall account for coseismic vertical displacement.

Table 6.7-1. Regional Waveform Parameters.

Region	a_1	a_2[a]	T_{TSU}[b]	N
Washington	1.0 H_T	−0.61 to −0.82 H_T	30 to 40 min	2
Oregon	1.0 H_T	−0.55 to −0.67 H_T	30 to 45 min	2
California – north inclusive of Cape Mendocino	1.0 H_T	−0.55 to −0.67 H_T	25 to 35 min	2
California – south of Cape Mendocino	1.0 H_T	−0.43 to −0.67 H_T	25 to 35 min	3
Alaska	1.0 H_T	−0.55 to −0.82 H_T	20 to 40 min	2
Hawaii	1.0 H_T	−0.67 to −1.0 H_T	25 to 30 min	3

[a] For a leading depression waveform, the trough of amplitude a_2 shall precede the crest of amplitude a_1.
[b] The value of T_{TSU} shall be used if no mapped value is given in Figure 6.7-1.

@seismicisolation

6.7.4 Treatment of Modeling and Natural Uncertainties A statistically weighted logic tree approach shall be used to account for epistemic uncertainties in the model parameters and shall provide a sample of tsunamigenic earthquakes and their occurrence probabilities from tectonic, geodetic, historical, and paleotsunami data, and estimated plate convergence rates, as follows:

1. Subdivide the occurrence probability systematically to account for variations in the parameters of magnitude, fault depth and geometry, and location, slip distribution, and rupture extent of events consistent with maximum magnitudes, and tidal variation considering at least the Reference Sea Level.
2. To the extent practical and quantifiable, follow a similar logic tree approach to determine samples of tsunami sources such as nonsubduction zone earthquakes, landslides, and volcanic eruptions.

Aleatory uncertainties, such as the natural variability in the source processes, modeling uncertainties, and tidal variation as they relate to nearshore processes and wave runup, shall be included in the probabilistic analysis. When accounting for long wave durations with multiple maxima in the tsunami time series, it shall be permitted to consider tidal variability by selecting a rational tidal elevation independently from a probabilistic distribution of tide stages for each wave maximum. Truncation of aleatory distributions shall be chosen at an appropriate level for the return period but shall not be less than one standard deviation based on a regression analysis of computed versus observed data of Section 6.7.6.7.2.

6.7.5 Offshore Tsunami Amplitude The probabilistic analysis shall be performed either by direct computation according to Section 6.7.5.2 or by performing a Probabilistic Tsunami Hazard Analysis for a region of interest to produce site-specific Offshore Tsunami Amplitude hazard maps and predominant wave period at 328 ft (100 m) depth in accordance with the following:

1. A Digital Elevation Model (DEM) from global, regional, and coastal data sets shall be used to cover the computational domain from the tsunami sources to the site. The bathymetry grid of the ocean shall have a DEM resolution finer than 4.35 mi (7,000 m), and the offshore model regime with depth greater than 656 ft (200 m) shall have a DEM resolution finer than 3,281 ft (1,000 m).
2. The Earth surface deformation shall be determined from the seismic source parameters using a planar fault model accounting for vertical changes to the seafloor.

6.7.5.1 Offshore Tsunami Amplitude for Distant Seismic Sources OFFSHORE TSUNAMI AMPLITUDE shall be probabilistically determined in accordance with the following:

1. A weighted combination of tsunami waveforms determined for each unit fault segment in accordance with the slip distribution shall be used to propagate tsunamis in deep water using the linear long wave equations, also termed the shallow water wave equations, where water depth is much less than the wavelength, to take into account spatial variations in seafloor depth.
2. The offshore wave amplitude distribution and associated wave parameters, including period, shall be determined for the design exceedance rate of the 2,475-year Maximum Considered Tsunami taking into consideration uncertainties per Section 6.7.4.
3. The analysis shall include the disaggregation of the seismic sources and associated moment magnitudes that together contribute at least 90% to the net offshore tsunami hazard at the site under consideration.
4. The extent of offshore tsunami amplitude points considered for the site shall include the following:
   (a) For sites within Washington, Oregon, California, and Hawaii, the extent shall include points within at least 40 mi (64.4 km) but not exceeding 50 mi (80.5 km) of projected length along the coastline, centered on the site within a tolerance of plus or minus 6 mi (9.7 km);
   (b) For sites within Alaska, the extent shall include points within at least 100 mi (161 km) but not exceeding 125 mi (201 km), centered on the site within a tolerance of plus or minus 15 mi (24.1 km);
   (c) For sites within bays, the designated center of the computed offshore tsunami amplitude points shall be taken either offshore of the mouth of the bay or centered in accordance with criteria (a) or (b) above, whichever produces the more severe flow conditions at the site.
   (d) For island locations where the projected width of the island is less than 40 mi (64.4 km), it shall be permitted to consider the extent of offshore tsunami amplitude points corresponding to the projected width of the island. Shorter extents of offshore tsunami amplitude points shall be permitted for island locations, but shall not be less than 10 mi (16.1 km). In addition, the tsunami source development and inundation modeling are subject to an independent peer review by a tsunami modeler approved by the Authority Having Jurisdiction, who shall present a written report to the Authority Having Jurisdiction as to the hazard consistency of the modeling with the requirements of Section 6.7.
5. The mean value of the computed offshore tsunami amplitudes shall be not less than 100% of the mean value for the coinciding offshore tsunami amplitude data given by the ASCE Tsunami Design Geodatabase.
6. The individual values of computed offshore tsunami wave amplitude shall be not less than 80% of the coinciding-offshore tsunami amplitude values given by the ASCE Tsunami Design Geodatabase.

6.7.5.2 Direct Computation of Probabilistic Inundation and Runup It shall be permitted to compute probabilistic inundation and runup directly from a probabilistic set of sources, source characterizations, and uncertainties consistent with Section 6.7.2, Section 6.7.4, and the computing conditions set out in Section 6.7.6. The offshore wave amplitudes computed shall comply with the requirements of Sections 6.7.5.1.4, 6.7.5.1.5, and 6.7.5.1.6.

6.7.5.3 Use of Higher-Order Tsunami Model Features Higher-order tsunami model features, including wave dispersion, elasticity of the earth, variation in gravity, water compressibility, or water density stratification, shall be permitted as analysis enhancements for use within the same model software and parameters selected to comply with Section 6.7, including but not limited to bathymetric and terrain data, grid configuration, and bottom friction, provided these features are also validated in accordance with Section 6.7.6.7 and the higher-order tsunami model satisfies the following conditions:

1. The computed offshore wave amplitudes comply with the requirements of Section 6.7.5.1, or the model with the

@seismicisolation

higher-order features complies with all of the following requirements:

(a) Sections 6.7.5.1.1 through 6.7.5.1.4,

(b) The mean value of the computed offshore tsunami amplitudes is at least 85% of the mean value for the coinciding offshore tsunami amplitude data of the ASCE Tsunami Design Geodatabase,

(c) The values of computed offshore tsunami wave amplitude are not less than 75% of the coinciding offshore tsunami amplitude values of the ASCE Tsunami Design Geodatabase.

(d) Documentation of the tsunami source development, inundation modeling features and their prior validations, computed offshore tsunami amplitudes and runups for the model, with and without the higher order features shall be subject to an independent peer review by a tsunami modeler approved by the Authority Having Jurisdiction, who shall present a written report to the Authority Having Jurisdiction as to the model's compliance with the requirements of Section 6.7.

2. Use of a tsunami model with higher-order features shall comply with the following procedure:

(a) The tsunami model without the higher-order features shall determine a Hazard Consistent Tsunami Scenario that satisfies the requirements of Sections 6.7.5.1.5 and 6.7.5.1.6.

(b) The Hazard Consistent Tsunami Scenario shall be used for the same tsunami model with its higher-order features engaged, and one of the following criteria shall be satisfied:

(i) If Section 6.7.5.1 is satisfied, then the results of the higher-order model shall be deemed acceptable;

(ii) If Section 6.7.5.3.1 is satisfied, then a report documenting the results of a peer review of the higher-order model results shall be submitted to the Authority Having Jurisdiction for approval;

If neither Section 6.7.5.1 nor Section 6.7.5.3.1 is satisfied, then the Hazard Consistent Tsunami Scenario shall be modified until one of the above criteria is satisfied using the higher-order model features.

6.7.6 Procedures for Determining Tsunami Inundation and Runup

6.7.6.1 Representative Design Inundation Parameters Each disaggregated tsunami event shall be analyzed to determine representative design parameters consisting of maxima of runup, inundation depth, flow velocity, and momentum flux.

6.7.6.2 Seismic Subsidence before Tsunami Arrival Where the seismic source is a local subduction event, the Maximum Considered Tsunami inundation shall be determined for an overall elevation subsidence value shown in Figure 6.7-3(a) and 6.7-3(b) or shall be directly computed for the seismic source mechanism. The GIS digital map layers of subsidence are available in the ASCE Tsunami Design Geodatabase at http://asce7tsunami.online.

6.7.6.3 Model Macroroughness Parameter It shall be permitted to perform inundation mapping under bare-earth conditions with macroroughness. Bed roughness shall be permitted to be prescribed using the Manning's coefficient, n. Unless otherwise determined for the site, a default value of 0.025 or 0.030 shall be used for the ocean bottom and on land. Use of other values based on terrain analysis shall be justified in the recognized literature or shall be specifically validated for the inundation model for field benchmarks of historical tsunami. Where values other than the defaults are used, the effects of degradation of roughness because of damaging flow characteristics shall be considered in the choice of Manning coefficient.

6.7.6.4 Nonlinear Modeling of Inundation Nonlinear shallow water wave equations or equivalent modeling techniques shall be used to transform the offshore wave amplitude from 328 ft (100 m) depth toward the shore to its nearshore tsunami amplitude and maximum inundation. The following effects shall be included as applicable to the bathymetry:

1. Shoaling, refraction, and diffraction to determine nearshore tsunami amplitude;
2. Dispersion effects in the case of short-wavelength sources, such as landslides and volcanic sources;
3. Reflected waves;
4. Channeling in bays;
5. Edge waves, and shelf and bay resonances;
6. Bore formation and propagation; and
7. Harbor and port breakwaters and levees.

6.7.6.5 Model Spatial Resolution A Digital Elevation Model (DEM) for the nearshore bathymetry depth of less than 656 ft (200 m) shall have a resolution not coarser than 295 ft (90 m). At bathymetric depths of less than 32.8 ft (10 m) and on land, the DEM shall have a resolution not coarser than the highest resolution available from the Tsunami Inundation Digital Elevation Models of the NOAA National Geophysical Data Center (NGDC). If a nested grid approach is used, the reduction in grid-spacing between consecutive grids shall not be more than a factor of 5. Where the NOAA NGDC models are not available, use of the best available USGS integrated Digital Elevation Model data shall be permitted when approved by the Authority Having Jurisdiction.

6.7.6.6 Built Environment If buildings and other structures are included for the purposes of more detailed flow analysis, the Digital Elevation Model resolution shall have a minimum resolution of 10 ft (3.0 m) to capture flow deceleration and acceleration in the built environment.

6.7.6.7 Inundation Model Validation

6.7.6.7.1 Historical or Paleotsunami Inundation Data Model scenario results shall be validated with available historical and/or paleotsunami records.

6.7.6.7.2 Model Validation by Benchmark Tests The inundation model shall be validated using the certification criteria of the National Tsunami Hazard Mitigation Program (NTHMP) within 10% by providing satisfactory performance in a series of benchmark tests of known data sets designated by the Tsunami Model Validation Advisory Group in NOAA Technical Memorandum OAR PMEL-135, "Standards, Criteria, and Procedures for NOAA Evaluation of Tsunami Numerical Models," as modified by the NTHMP.

6.7.6.7.3 Tsunami Bore Formation or Soliton Fission In regions where bore formation may occur, the model shall be validated with an independent scenario in the recognized literature, and acceptability shall be determined using modeled runup.

6.7.6.8 Determining Site-Specific Inundation Flow Parameters Inundation parameters for the scenarios from each disaggregated source region shall be determined. Probabilistic flow parameters shall be developed for the site

@seismicisolation

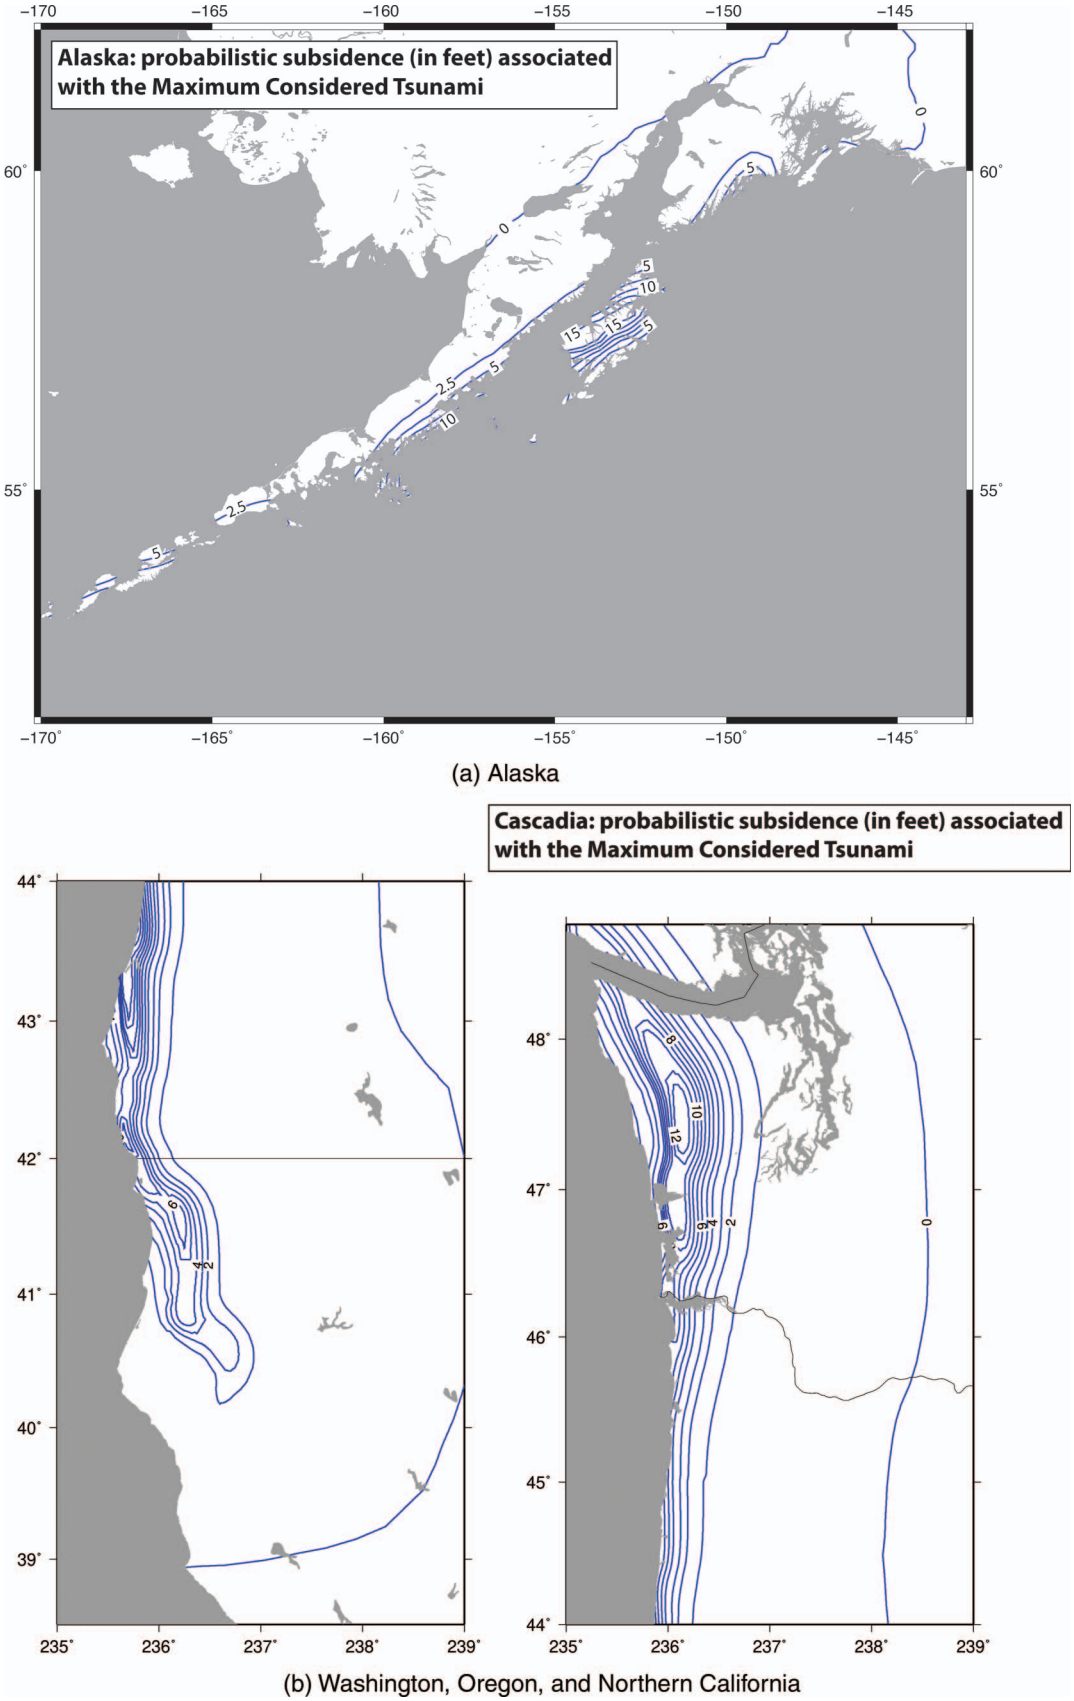

Figure 6.7-3. Earthquake-induced regional ground subsidence (in feet) associated with a Maximum Considered Tsunami caused by a local subduction earthquake (1 ft = 0.305 m).

Note: The GIS digital map layers of subsidence are available from the ASCE Tsunami Design Geodatabase at http://asce7tsunami.online.

@seismicisolation

from the sample of computed tsunamis and their occurrence probabilities. Each tsunami event shall be analyzed to determine representative parameters such as maximum runup, inundation depth, flow velocity, and/or specific momentum flux by either of the following techniques:

1. Taking the weighted average of the scenario runs that bracket the offshore wave amplitude for the return period to determine Hazard-Consistent Tsunami scenarios. The inundation limit shall be determined by the area that is inundated by the Hazard-Consistent Tsunami scenario waves from the disaggregated principal seismic source zones affecting that site corresponding to the Maximum Considered Tsunami return period.
2. Determining the probabilistic distributions of flow parameters from the sample of computed tsunamis and their occurrence probabilities and reconstructing statistical distributions of flow parameters of inundation depth, velocity, and specific momentum flux at the site from the computed scenarios for at least three load cases, as indicated in Section 6.8.10.

In urban environments, the resulting flow velocities at a given structure location shall not be reduced from 90% of those determined in accordance with Section 6.6 before any velocity adjustments caused by flow amplification. For other terrain roughness conditions, the resulting flow velocities at a given structure location shall not be taken as less than 75% of those determined in accordance with Section 6.6 before any velocity adjustments caused by flow amplification.

Where a site-specific inundation analysis spatially defines the topographic diversion of the direction of inundation flow across the Tsunami Design Zone, the minimum flow velocity limits for the site determined by Section 6.6 shall be permitted to be determined using angularly segmented transects that follow the site-specific inundation flow field vectors from shoreline to Runup, subject to the requirements of Section 6.8.6.2.

6.7.6.9 Tsunami Design Parameters for Flow over Land The flow parameters of inundation depth, flow velocity, and/or specific momentum flux at the site of interest shall be captured from a time history inundation analysis. Tsunami inundation depth and velocity shall be evaluated for the site at the stages of inundation defined by the load cases in Section 6.8.3.1. If the maximum momentum flux is found to occur at an inundation depth different than Load Case 2, the flow conditions corresponding to the maximum momentum flux shall be considered in addition to the load cases defined in Section 6.8.3.1.

6.8 STRUCTURAL DESIGN PROCEDURES FOR TSUNAMI EFFECTS

Structures, components, and foundations shall conform to the requirements of this section when subjected to the loads and effects of the Maximum Considered Tsunami.

6.8.1 Performance of Tsunami Risk Category II and III Buildings and Other Structures Structural components, connections, and foundations of Risk Category II buildings and Risk Category III buildings and other structures shall be designed to meet Collapse Prevention Structural Performance criteria or better.

6.8.2 Performance of Tsunami Risk Category III Critical Facilities and Tsunami Risk Category IV Buildings and Other Structures Tsunami Risk Category III Critical Facilities and Tsunami Risk Category IV buildings and other structures located within the Tsunami Design Zone shall be designed in accordance with the following requirements.

1. The operational nonstructural components and equipment of the building necessary for essential functions and the elevation of the bottom of the lowest horizontal structural member at the level supporting such components and equipment shall be above the inundation elevation of the Maximum Considered Tsunami.
2. Structural components and connections in occupiable levels and foundations shall be designed in accordance with Immediate Occupancy Structural Performance criteria. Occupiable levels shall be permitted where the elevation equals or exceeds the Maximum Considered Tsunami inundation elevation.
3. Tsunami Vertical Evacuation Refuge Structures shall also comply with Section 6.14.

6.8.3 Structural Performance Evaluation Strength and stability shall be evaluated to determine that the design of the structure is capable of resisting the tsunami at the Load Cases defined in Section 6.8.3.1. The structural acceptance criteria for this evaluation shall be in accordance with either Section 6.8.3.4 or 6.8.3.5.

6.8.3.1 Load Cases As a minimum, the following three inundation load cases shall be evaluated.

Load Case 1: At an exterior inundation depth not exceeding the maximum inundation depth nor the lesser of one story or the height of the top of the first-story windows, the minimum condition of combined hydrodynamic force with buoyant force shall be evaluated with respect to the depth of water in the interior. The interior water depth shall be evaluated in accordance with Section 6.9.1.

EXCEPTION: Load Case 1 need not be applied to Open Structures nor to structures where the soil properties or foundation and structural design prevent detrimental hydrostatic pressurization on the underside of the foundation and lowest structural slab.

Load Case 2: Depth at two-thirds of maximum inundation depth when the maximum velocity and maximum specific momentum flux shall be assumed to occur in either incoming or receding directions.

Load Case 3: Maximum inundation depth when velocity shall be assumed at one-third of maximum in either incoming or receding directions.

The inundation depths and velocities defined for Load Cases 2 and 3 shall be determined by Figure 6.8-1, unless a site-specific tsunami analysis is performed in accordance with Section 6.7.

6.8.3.2 Tsunami Importance Factors The Tsunami Importance Factors, I_{tsu}, given in Table 6.8-1 shall be applied to the tsunami hydrodynamic and impact loads in Sections 6.10 and 6.11, respectively.

6.8.3.3 Load Combinations Principal tsunami forces and effects shall be combined with other specified loads in accordance with the load combinations of Equation (6.8-1a):

$$0.9D + F_{TSU} + H_{TSU} \quad (6.8\text{-}1a)$$

$$1.2D + F_{TSU} + 0.5L + 0.2S + H_{TSU} \quad (6.8\text{-}1b)$$

@seismicisolation

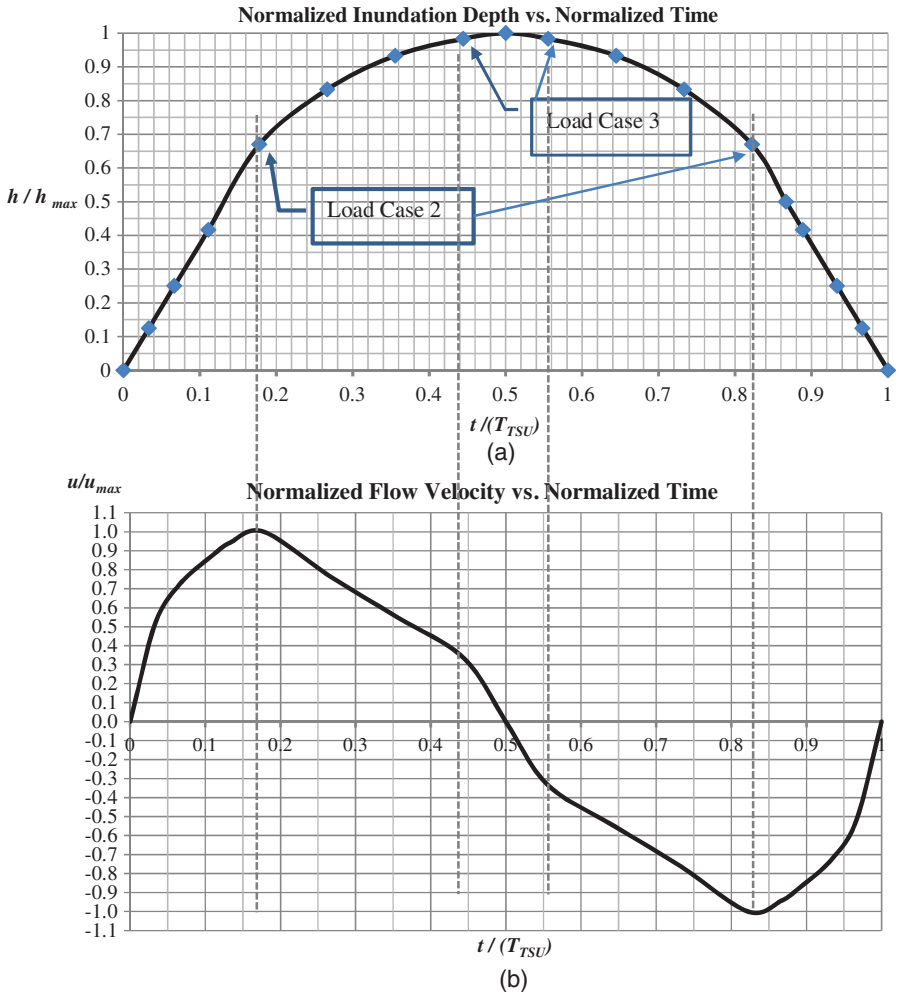

Figure 6.8-1. Inundation Load Cases 2 and 3.

Table 6.8-1. Tsunami Importance Fctors for Hydrodynamic and Impact Loads.

Tsunami Risk Category	I_{tsu}
II	1.0
III, Tsunami Risk Category IV, Vertical Evacuation Refuges, and Tsunami Risk Category III Critical Facilities	1.25
Tsunami Risk Category IV where the inundation depth is less than 12 ft (3.66 m) and a site-specific Probabilistic Tsunami Hazard Analysis is not performed, per the exception to Section 6.5.2	1.5

where

F_{TSU} = Tsunami load effect for incoming and receding directions of flow, and

H_{TSU} = Load caused by tsunami-induced lateral foundation pressures developed under submerged conditions. Where the net effect of H_{TSU} counteracts the principal load effect, the load factor for H_{TSU} shall be 0.9.

6.8.3.4 Lateral-Force-Resisting System Acceptance Criteria For structures designed to the requirements for Seismic Design Category A, B, or C, the lateral-force-resisting system shall be designed to resist the Maximum Considered Tsunami. For structures designed to the requirements for Seismic Design Category D, E, or F, the lateral-force-resisting system shall be deemed adequate if 0.75 $\Omega_0 E_h$ exceeds the required tsunami force F_{TSU}, where E_h is the required seismic resistance and Ω_0 is the system overstrength as defined in Chapter 12 of this standard. If the value of 0.75 $\Omega_0 E_h$ does not exceed F_{TSU}, the lateral-force-resisting system at all levels below the maximum inundation depth shall be designed for a minimum seismic force $Q_E \geq F_{TSU}/(0.75\ \Omega_0)$, or the lateral-force-resisting system shall be explicitly analyzed to validate its resistance to the Maximum Considered Tsunami. For Immediate Occupancy Structural Performance objectives, the lateral-force-resisting system shall be explicitly analyzed and evaluated.

6.8.3.5 Structural Component Acceptance Criteria Structural components shall be designed for the forces that result from the

@seismicisolation

overall tsunami forces on the structural system combined with any resultant actions caused by the tsunami pressures acting locally on the individual structural components for that direction of flow. Acceptance criteria of structural components shall be in accordance with Section 6.8.3.5.1, or in accordance with alternative procedures of 6.8.3.5.2 or 6.8.3.5.3, as applicable.

6.8.3.5.1 Acceptability Criteria by Component Design Strength Internal forces and system displacements shall be determined using a linearly elastic, static analysis. The structural performance criteria required in Section 6.8.1, Section 6.8.2, and Section 6.8.3, as applicable, shall be deemed to comply if the design strength of the structural components and connections are shown to be greater than the Maximum Considered Tsunami loads and effects computed in accordance with the load combinations of Section 6.8.3.3. Material resistance factors, φ, shall be used as prescribed in the material-specific standards for the component and behavior under consideration.

6.8.3.5.2 Alternative Performance-Based Criteria

6.8.3.5.2.1 Alternative Analysis Procedures It shall be permitted to use either a linear or a nonlinear static analysis procedure. In a linear static analysis procedure, buildings and structures shall be modeled using an equivalent effective stiffness consistent with the secant value at or near the yield point. For a nonlinear static analysis procedure, a mathematical model directly incorporating the nonlinear load-deformation characteristics of individual components of the structure shall be subjected to monotonically increasing loads until the required tsunami forces and applied actions are reached. For nonlinear static analysis procedures, expected deformation capacities shall be greater than or equal to the maximum deformation demands calculated at the required tsunami forces and applied actions. For debris impacts, it shall be permitted to use a nonlinear dynamic analysis procedure. For Tsunami Risk Category IV buildings and structures, an independent peer review shall be conducted as part of a review of the performance-based design by the Authority Having Jurisdiction.

6.8.3.5.2.2 Alternative Structural Component Acceptability Criteria All actions shall be classified as either ductility-governed actions or force-sustained actions based on component inelastic behavior and the duration of the load effect, as follows:

1. Fluid forces in primary and secondary structural components detailed in accordance with the requirements of Seismic Design Category D, E, or F shall be evaluated as force-sustained actions.
2. Debris impacts and foundation settlement effects on primary and secondary structural components shall be evaluated as ductility-governed actions.
3. Debris impacts and foundation settlement effects on primary and secondary structural components not detailed in accordance with Seismic Design Category D, E, or F shall be evaluated as force-sustained actions.

For force-sustained actions, structural components shall have specified design strengths greater than or equal to the maximum design forces. Force-sustained actions shall be permitted to satisfy Equation (6.8-2):

$$Q_{CS} \geq Q_{UF} \tag{6.8-2}$$

where Q_{CS} is the specified strength of the structural element and Q_{UF} is the maximum force generated in the element because of gravity and tsunami loading.

Expected material properties as defined in ASCE 41 shall be permitted to be used for ductility-governed actions. Results of a linear analysis procedure shall not exceed the component acceptance criteria for linear procedures of ASCE 41, Chapters 9 through 11, for the applicable structural performance criteria required for the building or structure tsunami risk category. Ductility-governed actions shall be permitted to satisfy Equation (6.8-3):

$$mQ_{CE} \geq Q_{UD} \tag{6.8-3}$$

where

m = Value of the component demand modification factor defined in ASCE 41 to account for expected ductility at the required structural performance level;
Q_{CE} = Expected strength of the structural element determined in accordance with ASCE 41; and
Q_{UD} = Ductility-governed force caused by tsunami loading.

6.8.3.5.3 Alternative Acceptability by Progressive Collapse Avoidance Where tsunami loads or effects exceed acceptability criteria for a structural element or where required to accommodate extraordinary impact loads, it shall be permitted to check the residual load-carrying capacity of the structure, assuming that the element has failed, in accordance with Section 2.5.2.2 and an alternate load path progressive collapse procedure in the recognized literature.

6.8.4 Minimum Fluid Density for Tsunami Loads Seawater specific weight density, γ_{sw}, shall be taken as 64.0 lb/ft^3 (10 kN/m^3). Seawater mass density, ρ_{sw}, shall be taken as 2.0 sl/ft^3 (1,025 kg/m^3). The minimum fluid specific weight density, γ_s, for determining tsunami hydrostatic loads accounting for suspended solids and debris flow-embedded smaller objects shall be

$$\gamma_s = k_s \gamma_{sw} \tag{6.8-4}$$

The minimum fluid mass density, ρ_s, for determining tsunami hydrodynamic loads accounting for suspended solids and debris flow-embedded smaller objects shall be

$$\rho_s = k_s \rho_{sw} \tag{6.8-5}$$

where k_s, the fluid density factor, shall be taken as 1.1.

6.8.5 Flow Velocity Amplification The effect of upstream obstructing buildings and structures shall be permitted to be considered at a site that is exposed to the flow diffracting conditions given in Section 6.8.5.1 by any of the following:

1. A site-specific inundation analysis that includes modeling of the built environment in accordance with Section 6.7.6.6, or
2. The built environment is considered in the selection of Manning's roughness of Table 6.6-1 in accordance with the Energy Grade Line Analysis of Section 6.6.2, or
3. Site-specific physical or numerical modeling in accordance with Section 6.8.5.2 or Section 6.8.10, as applicable.

6.8.5.1 Upstream Obstructing Structures The effect of upstream obstructions on flow shall be considered where the obstructions are enclosed structures of concrete, masonry, or structural steel construction located within 500 ft (152 m) of the site, and both of the following apply:

@seismicisolation

1. Structures have plan width greater than 100 ft (30.5 m) or 50% of the width of the downstream structure, whichever is greater; and
2. The structures exist within the sector between 10 and 55 degrees to either side of the flow vector aligned with the center third of the width of the downstream structure.

6.8.5.2 Flow Velocity Amplification by Physical or Numerical Modeling The effect of upstream structures on the flow velocity at a downstream site shall be permitted to be evaluated using site-specific numerical or physical modeling, as described in Section 6.7.6.6 or 6.8.10. The velocity determined for a "bare-earth" inundation shall be amplified for the conditions of Section 6.8.5.1. This analysis is not permitted to reduce the flow velocity except for structural countermeasures designed in accordance with Section 6.13.

6.8.6 Directionality of Flow

6.8.6.1 Flow Direction Design of structures for tsunami loads and effects shall consider both incoming and outgoing flow conditions. The principal inflow direction shall be assumed to vary by ±22.5 degrees from the transect perpendicular to the orientation of the shoreline averaged over 500 ft (152 m) to either side of the site. The center of rotation of the variation of transects shall be located at the geometric center of the structure in plan at the grade plane.

6.8.6.2 Site-Specific Directionality A site-specific inundation analysis performed in accordance with Section 6.7.6 shall be permitted to be used to determine directionality of flow, provided that the directionalities so determined shall be assumed to vary by at least ±10 degrees.

6.8.7 Minimum Closure Ratio for Load Determination Loads on buildings shall be calculated assuming a minimum closure ratio of 70% of the inundated projected area along the perimeter of the structure, unless it is an Open Structure as defined in Section 6.2. The load effect of debris accumulation against or within the Open Structure shall be considered by using a minimum closure ratio of 50% of the Inundated Projected Area along the perimeter of the Open Structure. Open Structures need not be subject to Load Case 1 of Section 6.8.3.1.

6.8.8 Minimum Number of Tsunami Flow Cycles Design shall consider a minimum of two tsunami inflow and outflow cycles, the first of which shall be based on an inundation depth at 80% of the Maximum Considered Tsunami (MCT), and the second of which shall be assumed to occur with the MCT inundation depth at the site. Local scour effects caused by the first cycle, and determined in accordance with Section 6.12, shall be assumed to occur at 80% of the MCT inundation depth at the site and shall be considered as an initial condition of the second cycle.

6.8.9 Seismic Effects on the Foundations Preceding Local Subduction Zone Maximum Considered Tsunami Where designated in Figure 6.7-3 as a site subject to a local subduction zone tsunami from an offshore subduction earthquake, the structure shall be designed for the preceding coseismic effects. The foundation of the structure shall be designed to resist the preceding earthquake ground motion and its associated effects per Chapter 11 of this standard using the Maximum Considered Earthquake Geometric Mean (MCE_G) Peak Ground Acceleration of Figures 22-7, 22-8, and 22-9. Building foundation design shall include changes in the site surface and the in situ soil properties resulting from the design seismic event as initial conditions for the subsequent design tsunami event. The geotechnical investigation report shall include evaluation of foundation effects in reference to seismic effects preceding the tsunami, with consideration of slope instability, liquefaction, total and differential settlement, surface displacement caused by faulting, and seismically induced lateral spreading or lateral flow. The additional requirements of Section 6.12 shall also be evaluated.

6.8.10 Physical Modeling of Tsunami Flow, Loads, and Effects Physical modeling of tsunami loads and effects shall be permitted as an alternative to the prescriptive procedures in Sections 6.8.5 (flow velocity amplification), 6.10 (hydrodynamic loads), 6.11 (debris impact loads), and 6.12 (foundation design), provided that it meets all the following criteria.

1. The facility or facilities used for physical modeling shall be capable of generating appropriately scaled flows and inundation depths as specified for Load Cases in Section 6.8.3.1.
2. The test facility shall be configured so that reflections and edge effects shall not significantly affect the test section during the duration of the experiments.
3. The scale factors used in the physical modeling shall not be less than those shown in Table 6.8-2. Scale model tests not directly addressed in Table 6.8-2 shall include a justification of the model applicability and scaling procedures.
4. Debris impacts of full or partial components shall be tested at full scale unless accompanied by a justification of the appropriateness of scaled testing in terms of hydrodynamics and structural mechanics as well as material properties.
5. The report of test results shall include a discussion of the accuracy of load condition generation and scale effects caused by dynamic and kinematic considerations, including dynamic response of test structures and materials.
6. Test results shall be adjusted to account for effective density, as calculated in Section 6.8.4.
7. Test results shall be adjusted by the Importance Factor from Section 6.8.3.2.
8. Test results shall include the effects of flow directionality in accordance with Section 6.8.6. This inclusion can be accomplished either by direct testing of flow at varying angles of incidence or by a combination of numerical and physical modeling that takes into account directionality of flow.

6.9 HYDROSTATIC LOADS

6.9.1 Buoyancy Reduced net weight caused by buoyancy shall be evaluated for all inundated structural and designated nonstructural elements of the building in accordance with Equation (6.9-1).

$$F_v = \gamma_s V_w \tag{6.9-1}$$

Table 6.8-2. Minimum Scale Factors for Physical Modeling.

Model Element	Minimum Scale Factor
Individual buildings	1:25
Flow modeling for groups of buildings	1:200
Structural components (e.g., walls, columns, piers)	1:10
Geotechnical investigations	1:5

@seismicisolation

Uplift caused by buoyancy shall include enclosed spaces without tsunami breakaway walls that have an opening area less than 25% of the inundated exterior wall area. Buoyancy shall also include the effect of air trapped below floors, including integral structural slabs, and in enclosed spaces where the walls are not designed to break away. All windows, except those designed for large missile wind-borne debris impact or blast loading, shall be permitted to be considered openings when the inundation depth reaches the top of the windows or the expected strength of the glazing, whichever is less. The volumetric displacement of foundation elements, excluding deep foundations, shall be included in this calculation of uplift.

6.9.2 Unbalanced Lateral Hydrostatic Force Inundated structural walls with openings less than 10% of the wall area and either longer than 30 ft (9.14 m) without adjacent tsunami breakaway walls, or having a two- or three-sided perimeter structural wall configuration regardless of length, shall be designed to resist an unbalanced hydrostatic lateral force given by Equation (6.9-2), occurring during the Load Case 1 and the Load Case 2 inflow cases defined in Section 6.8.3.1.

Where the flow does not overtop the wall, the lateral hydrostatic force on the wall shall be determined using Equation (6.9-2).

$$F_h = \frac{1}{2}\gamma_s b h^2 \tag{6.9-2}$$

Where the flow overtops the wall, the lateral hydrostatic force on the wall shall be determined using Equation (6.9-3).

$$F_h = 0.6\gamma_s(2h - h_w)bh_w \tag{6.9-3}$$

6.9.3 Residual Water Surcharge Load on Floors and Walls All horizontal floors below the maximum inundation depth shall be designed for dead load plus a residual water surcharge pressure, p_r, given by Equation (6.9-4).

$$p_r = \gamma_s h_r \quad \text{where } h_r = h_{\max} - h_s \tag{6.9-4}$$

where h_s is the top of floor slab elevation. However, h_r need not exceed the height of the continuous portion of any perimeter structural element at the floor.

Structural walls that have the potential to retain water during drawdown shall also be designed for residual water hydrostatic pressure.

6.9.4 Hydrostatic Surcharge Pressure on Foundation Hydrostatic surcharge pressure caused by tsunami inundation shall be calculated as

$$p_s = \gamma_s h_{\max} \tag{6.9-5}$$

6.10 HYDRODYNAMIC LOADS

Hydrodynamic loads shall be determined in accordance with this section. The structure's lateral-force-resisting system and all structural components below the inundation elevation at the site shall be designed for the hydrodynamic loads given in either Section 6.10.1 or 6.10.2. All wall and slab components shall also be designed for all applicable loads given in Section 6.10.3.

6.10.1 Simplified Equivalent Uniform Lateral Static Pressure It shall be permitted to account for the combination of any unbalanced lateral hydrostatic and hydrodynamic loads by applying an equivalent maximum uniform pressure, p_{uw}, determined in accordance with Equation (6.10-1), applied over 1.3 times the calculated maximum inundation depth, $h_{\max}$, at the site, in each direction of flow.

$$p_{uw} = 1.25 I_{\text{tsu}} \gamma_s h_{\max} \tag{6.10-1}$$

6.10.2 Detailed Hydrodynamic Lateral Forces

6.10.2.1 Overall Drag Force on Buildings and Other Structures The building's lateral-force-resisting system shall be designed to resist overall drag forces at each level caused either by incoming or outgoing flow at Load Case 2 given by Equations (6.10-2) and (6.10-3):

$$F_{dx} = \frac{1}{2}\rho_s I_{tsu} C_d C_{cx} B(h_{sx} u^2) \tag{6.10-2}$$

where C_d is the drag coefficient for the building as given in Table 6.10-1, and where C_{cx} is determined as

$$C_{cx} = \frac{\sum(A_{\text{col}} + A_{\text{wall}}) + 1.5A_{\text{beam}}}{Bh_{sx}} \tag{6.10-3}$$

and where A_{col} and A_{wall} are the vertical projected areas of all individual column and wall elements, and A_{beam} is the combined vertical projected area of the slab edge facing the flow and the deepest beam laterally exposed to the flow. The summation of these column, wall, and beam areas is divided by the overall building wall area of width B times the average of the story heights, h_{sx}, above and below each level for each story below the tsunami inundation height, for each of the three load cases specified in Section 6.8.3.1. Any structural or nonstructural wall that is not a tsunami breakaway wall shall be included in the A_{wall}. C_{cx} shall not be taken as less than the closure ratio value given in Section 6.8.7 but need not be taken as greater than 1.0.

6.10.2.2 Drag Force on Components The lateral hydrodynamic load given by Equation (6.10-4) shall be applied as a pressure resultant on the projected inundated height, h_e, of all structural components and exterior wall assemblies below the inundation depth:

$$F_d = \frac{1}{2}\rho_s I_{\text{tsu}} C_d b(h_e u^2) \tag{6.10-4}$$

Table 6.10-1. Drag Coefficients for Rectilinear Structures.

Width to Inundation Depth* Ratio, *B/h*	Drag Coefficient, C_d
≤12	1.25
60	1.75
≥120	2.0

* Inundation depth for each of the three Load Cases of inundation specified in Section 6.8.3.1. Interpolation shall be used for intermediate values of width to inundation depth ratio *B/h*. Where building setbacks occur, drag coefficients shall be determined for each portion of a constant width. For each portion along the inundated height of the building, its equivalent inundated depth is taken as its submerged vertical dimension.

@seismicisolation

Table 6.10-2. Drag Coefficients for Structural Components.

Structural Element Section	Drag Coefficient, C_d
Round column or equilateral polygon with six sides or more	1.2
Rectangular column of at least 2:1 aspect ratio with longer face oriented parallel to flow	1.6
Triangular column pointing into flow	1.6
Freestanding wall submerged in flow	1.6
Square or rectangular column with longer face oriented perpendicular to flow	2.0
Triangular column pointing away from flow	2.0
Wall or flat plate, normal to flow	2.0
Diamond-shape column, pointed into the flow (based on face width, not projected width)	2.5
Rectangular beam, normal to flow	2.0
I, L, and channel shapes	2.0

where for interior components, except vertical load-bearing components in storage warehouses, and truck and bus garages, the values of C_d given in Table 6.10-2 shall be used, and b is the component width perpendicular to the flow. For exterior components, a C_d value of 2.0 shall be used, and width dimension b shall be taken as the tributary width multiplied by the closure ratio value given in Section 6.8.7. For interior vertical load-bearing components in storage warehouses, a C_d value of 2.0 shall be used, and width dimension b shall be taken as 9 ft (2.74 m) or the length of structural wall, whichever is greater. For interior vertical load-bearing components in truck and bus garages, a C_d value of 2.0 shall be used, and width dimension b shall be taken as 40 ft (12.19 m), or the tributary width multiplied by the closure ratio value given in Section 6.8.7, whichever is smaller.

The drag force on component elements shall not be additive to the overall drag force computed in Section 6.10.2.1.

6.10.2.3 Tsunami Loads on Vertical Structural Components, F_w The force F_w on vertical structural components shall be determined as the hydrodynamic drag forces in accordance with Equation (6.10-5a). Where flow of a tsunami bore occurs with a Froude number at the site that is greater than 1.0 and where individual wall, wall pier, or column components have a width-to-inundation-depth ratio of 3 or more, F_w shall be determined by Equation (6.10-5b). The following two conditions shall be considered: (1) force F_w applied to all vertical structural components that are wider than three times the inundation depth corresponding to Load Case 2 during inflow as defined in Section 6.8.3, and (2) force F_w based on an inundation depth equal to one-third of the structural wall width, with the corresponding flow velocity determined using Figure 6.8-1.

$$F_w = \frac{1}{2}\rho_s I_{\text{tsu}} C_d b (h_e u^2) \tag{6.10-5a}$$

$$F_w = \frac{3}{4}\rho_s I_{\text{tsu}} C_d b (h_e u^2)_{\text{bore}} \tag{6.10-5b}$$

6.10.2.4 Hydrodynamic Load on Perforated Walls, F_{pw} For walls with openings that allow flow to pass between wall piers, the force on the elements of the perforated wall, F_{pw}, shall be permitted to be determined using Equation (6.10-6), but shall not be less than F_d per Equation (6.10-4).

$$F_{pw} = (0.4C_{cx} + 0.6)F_w \tag{6.10-6}$$

6.10.2.5 Walls Angled to the Flow For walls oriented at an angle less than 90 degrees to the flow directions considered in Section 6.8.3, the transient lateral load per unit width, $F_{w\theta}$, shall be determined in accordance with Equation (6.10-7).

$$F_{w\theta} = F_w \sin^2\theta \tag{6.10-7}$$

where θ is the included angle between the wall and the direction of the flow.

6.10.2.6 Loads on Above-Ground Horizontal Pipelines Above-ground horizontal pipelines necessary for the functionality of Tsunami Risk Category III and IV buildings and other structures shall be designed to resist the loads given in Sections 6.10.2.6.1 and 6.10.2.6.2.

6.10.2.6.1 Hydrodynamic Loads on Above-Ground Horizontal Pipelines The horizontal force per unit length shall be calculated as

$$F_{rp} = C_{cp} C_r \rho_s I_{\text{tsu}} D_p u^2 \tag{6.10-8}$$

where

$C_{cp} = 1.5$;
C_r = Pipe resistance coefficient as given in Table 6.10-3 or Figure 6.10-1;
ρ_s = Minimum fluid mass density for design hydrodynamic loads;
I_{tsu} = Importance Factor;
D_p = Pipe diameter; and
u = Tsunami flow velocity.

Table 6.10-3. Pipe Resistance Coefficient, C_r.

Froude number, F_r	Resistance Coefficient, C_r
$0 < F_r < 0.25$	3.6
$0.25 < F_r < 1.3$	$4.22 - 2.48F_r$
$1.3 < F_r < 2.75$	1.0

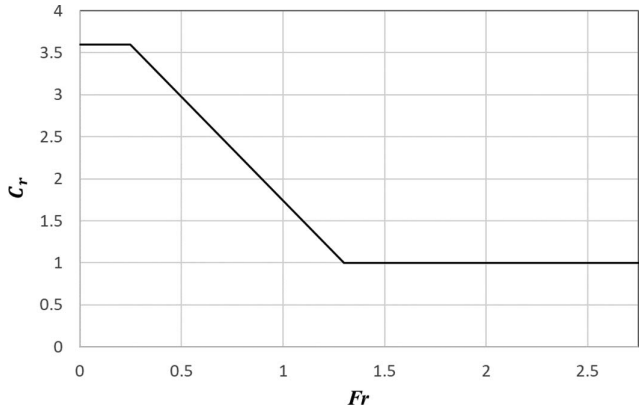

Figure 6.10-1. Pipe resistance coefficient, C_r, as a function of the Froude number, F_r.

@seismicisolation

Table 6.10-4. Upward Lift Coefficient, C_l^+, for Pipelines.

Froude number, F_r	Upward Lift Coefficient, C_l^+
$0 < F_r < 0.25$	2.8
$0.25 < F_r < 1.3$	$3.23 - 1.71F_r$
$1.3 < F_r < 2.75$	1.0

Table 6.10-5. Downward Lift Coefficient, C_l^-, for Pipelines.

Froude number, F_r	Downward Lift Coefficient, C_l^-
$0 < F_r < 0.25$	–2.8
$0.25 < F_r < 1.3$	$2.19\ F_r - 3.35$
$1.3 < F_r < 2.75$	–0.5

The upward vertical force per unit length shall be calculated as

$$F_{l+} = C_{cp} C_l^+ \rho_s I_{tsu} D_p u^2 \quad (6.10\text{-}9)$$

where

$C_{cp} = 1.5$,
C_l^+ = Upward lift coefficient as given in Table 6.10-4 or in Figure 6.10-2,
ρ_s = Minimum fluid mass density for design hydrodynamic loads,
I_{tsu} = Importance Factor,
D_p = Pipe diameter, and
u = Tsunami flow velocity.

The downward vertical force per unit length shall be calculated as

$$F_{l-} = C_{cp} C_l^- \rho_s I_{tsu} D_p u^2 \quad (6.10\text{-}10)$$

where

$C_{cp} = 1.5$,
C_l^- = Downward lift coefficient as given in Table 6.10-5 or in Figure 6.10-3,
ρ_s = Minimum fluid mass density for design hydrodynamic loads,
I_{tsu} = Importance Factor,
D_p = Pipe diameter, and
u = Tsunami flow velocity.

6.10.2.6.2 Debris Impacts on Above-Ground Horizontal Pipelines Debris impact loads on above-ground horizontal pipelines shall be in accordance with Section 6.11.

6.10.3 Hydrodynamic Pressures Associated with Slabs

6.10.3.1 Flow Stagnation Pressure The walls and slabs of spaces in buildings that are subject to flow stagnation pressurization shall be designed to resist pressure determined in accordance with Equation (6.10-11).

$$P_p = \frac{1}{2} \rho_s I_{tsu} u^2 \quad (6.10\text{-}11)$$

where u is the maximum free flow velocity at that location and load case.

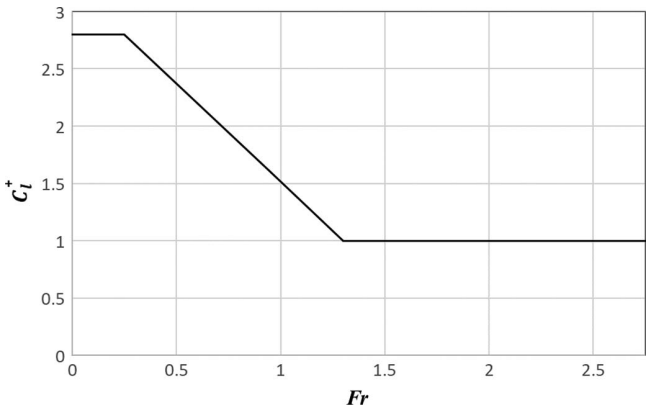

Figure 6.10-2. Upward lift coefficient, C_l^+, as a function of the Froude number, F_r.

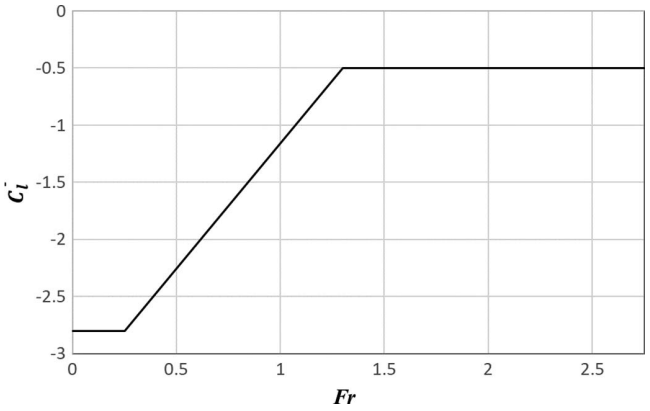

Figure 6.10-3. Downward lift coefficient, C_l^-, as a function of the Froude number, F_r.

6.10.3.2 Hydrodynamic Surge Uplift at Elevated Horizontal Slabs Slabs and other horizontal components shall be designed to resist the applicable uplift pressures given in this section.

6.10.3.2.1 Slabs Submerged during Tsunami Inflow Horizontal slabs that become submerged during tsunami inundation inflow shall be designed for a minimum hydrodynamic uplift pressure of 20 lb/ft^2 (0.958 kPa) applied to the soffit of the slab. This uplift is an additional Load Case to any hydrostatic buoyancy effects required by Section 6.9.1.

6.10.3.2.2 Slabs over Sloping Grade Horizontal slabs located over grade slope, φ, greater than 10 degrees shall be designed for a redirected uplift pressure applied to the soffit of the slab, given by Equation (6.10-12), but not less than 20 lb/ft^2 (0.958 kPa).

$$P_u = 1.5 I_{tsu} \rho_s u_v^2 \quad (6.10\text{-}12)$$

where

$u_v = u \tan \varphi$;
u = Horizontal flow velocity corresponding to a water depth equal to or greater than h_{ss}, the elevation of the soffit of the floor system; and
φ = Average slope of grade plane beneath the slab.

6.10.3.3 Tsunami Bore Flow Entrapped in Structural Wall-Slab Recesses Hydrodynamic loads for bore flows entrapped in structural wall-slab recesses shall be determined in accordance

@seismicisolation
@seismicisolation

with this section. The reductions of load given in Sections 6.10.3.3.2 to 6.10.3.3.5 may be combined multiplicatively, but the net load reduction shall not exceed the maximum individual reduction given by any one of these sections.

6.10.3.3.1 Pressure Load in Structural Wall-Slab Recesses Where flow of a tsunami bore beneath an elevated slab is prevented by a structural wall located downstream of the upstream edge of the slab, the wall and the slab within h_s of the wall shall be designed for the outward pressure, P_u, of 350 lb/ft^2 (16.76 kPa). Beyond h_s, but within a distance of $h_s + l_w$ from the wall, the slab shall be designed for an upward pressure of half of P_u [i.e., 175 lb/ft^2 (8.38 kPa)]. The slab outside a distance of $h_s + l_w$ from the wall shall be designed for an upward pressure of 30 lb/ft^2 (1.436 kPa).

6.10.3.3.2 Reduction of Load with Inundation Depth Where the inundation depth is less than two-thirds of the clear story height, the uplift pressures specified in Section 6.10.3.3.1 shall be permitted to be reduced in accordance with Equation (6.10-13) but shall not be taken as less than 30 lb/ft^2 (1.436 kPa).

$$P_u = I_{\text{tsu}}\left(590 - 160\frac{h_s}{h}\right)[\text{lb/ft}^2] \tag{6.10-13}$$

$$P_u = I_{\text{tsu}}\left(28.25 - 7.66\frac{h_s}{h}\right)[\text{kPa}] \tag{6.10-13.SI}$$

where h_s/h is the ratio of slab height to inundation depth.

6.10.3.3.3 Reduction of Load for Wall Openings Where the wall blocking the bore below the slab has openings through which the flow can pass, the reduced pressure on the wall and slab shall be determined in accordance with Equation (6.10-14).

$$P_{ur} = C_{cx}P_u \tag{6.10-14}$$

where C_{cx} is the ratio of the solid area of the wall to the total inundated area of the vertical plane of the inundated portion of the wall at that level.

6.10.3.3.4 Reduction in Load for Slab Openings Where the slab is provided with an opening gap or breakaway panel designed to create a gap of width w_g adjacent to the wall, then the uplift pressure on the remaining slab shall be determined in accordance with Equation (6.10-15).

$$P_{ur} = C_{bs}P_u \tag{6.10-15}$$

$$\text{where for } w_g < 0.5h_s,\ C_{bs} = 1 - \frac{w_g}{h_s} \tag{6.10-16}$$

$$\text{and for } w_g \geq 0.5h_s,\ C_{bs} = 0.56 - 0.12\frac{w_g}{h_s} \tag{6.10-17}$$

The value of C_{bs} shall not be taken as less than zero.

6.10.3.3.5 Reduction in Load for Tsunami Breakaway Wall If the wall restricting the flow is designed as a tsunami breakaway wall, then the uplift on the slab shall be permitted to be determined in accordance with Section 6.10.3.1, but it need not exceed the pressure equivalent to the total nominal shear force necessary to cause disengagement of the breakaway wall from the slab.

6.11 DEBRIS IMPACT LOADS

Debris impact loads shall be determined in accordance with this section. These loads need not be combined with other tsunami-related loads as determined in other sections of this chapter.

Where the minimum inundation depth is 3 ft (0.914 m) or greater, design shall include the effects of debris impact forces. The most severe effect of impact loads within the inundation depth shall be applied to the perimeter gravity-load-carrying structural components located on the principal structural axes perpendicular to the range of inflow or outflow directions defined in Section 6.8.7. Except as specified below, loads shall be applied at points critical for flexure and shear on all such members in the inundation depth being evaluated. Inundation depths and velocities corresponding to Load Cases 1, 2, and 3, defined in Section 6.8.3.1, shall be used. Impact loads need not be applied simultaneously to all affected structural components.

All buildings and other structures meeting the above requirement shall be designed for impact by floating wood poles, logs, and vehicles, and for tumbling boulders and concrete debris, per Sections 6.11.2 to 6.11.4. Where a site is proximate to a port or container yard, the potential for strikes from shipping containers and ships and barges shall be determined by the procedure in Section 6.11.5. Buildings and other structures determined by that procedure to lie in the hazard zone for strikes by shipping containers shall be designed for impact loads in accordance with Section 6.11.6. In lieu of Sections 6.11.2 to 6.11.6, it shall be permitted to alternatively evaluate the impacts by poles, logs, vehicles, tumbling boulders, concrete debris, and shipping containers by applying the alternative simplified static load of Section 6.11.1.

Where a building or other structure falls into one or more of the following categories, interior gravity-load-carrying structural components subject to inundation shall be designed for the specified debris impact:

1. Garages: vehicle debris impact per Section 6.11.3.
2. Open Structures with slab-on-grade at ground level: submerged tumbling boulder and concrete debris impact per Section 6.11.4, except where the slab-on-grade is explicitly designed per Section 6.12.4.2.
3. Buildings and other structures in which the slab-on-grade at ground level has isolation joints designed to reduce buoyancy effects: submerged tumbling boulder and concrete debris impact per Section 6.11.4.
4. Buildings with isolated breakaway concrete slab panels above grade designed to dislodge and relieve hydrodynamic uplift forces: the columns and structural walls nearest to the breakaway panels in all directions shall be designed for submerged tumbling boulder and concrete debris impact per Section 6.11.4.

Tsunami Risk Category III Critical Facilities and Tsunami Risk Category IV buildings and structures determined to be in the hazard zone for strikes by ships and barges in excess of 88,000 lb (39,916 kg) Deadweight Tonnage (DWT), as determined by the procedure of Section 6.11.5, shall be designed for impact by these vessels in accordance with Section 6.11.7.

6.11.1 Alternative Simplified Debris Impact Static Load It shall be permitted to account for debris impact by applying the force given by Equation (6.11-1) as a maximum static load, in lieu of the loads defined in Sections 6.11.2 to 6.11.6. This force shall be applied at points critical for flexure and shear on all such members in the inundation depth corresponding to Load Case 3 defined in Section 6.8.3.1.

@seismicisolation

$$F_i = 330 C_o I_{tsu} [\text{kips}] \quad (6.11\text{-}1)$$

$$F_i = 1,470 C_o I_{tsu} [\text{kN}] \quad (6.11\text{-}1.\text{SI})$$

where C_o is the orientation coefficient, equal to 0.65.

Where it is determined by the site hazard assessment procedure of Section 6.11.5 that the site is not in an impact zone for shipping containers, ships, and barges, then it shall be permitted to reduce the simplified debris impact force to 50% of the value given by Equation (6.11-1).

6.11.2 Wood Logs and Poles The nominal maximum instantaneous debris impact force, F_{ni}, shall be determined in accordance with Equation (6.11-2).

$$F_{ni} = u_{max} \sqrt{k m_d} \quad (6.11\text{-}2)$$

The design instantaneous debris impact force, F_i, shall be determined in accordance with Equation (6.11-3).

$$F_i = I_{tsu} C_o F_{ni} \quad (6.11\text{-}3)$$

where

I_{tsu} = Importance Factor (given in Table 6.8-1);
C_o = Orientation coefficient, equal to 0.65 for logs and poles;
u_{max} = Maximum flow velocity at the site occurring at depths sufficient to float the debris;
k = Effective stiffness of the impacting debris or the lateral stiffness of the impacted structural element(s) deformed by the impact, whichever is less; and
m_d = Mass (W_d/g) of the debris.

Logs and poles are assumed to strike longitudinally for calculation of debris stiffness in Equation (6.11-2). The stiffness of the log or pole shall be calculated as $k = EA/L$, in which E is the longitudinal modulus of elasticity of the log, A is its cross-sectional area, and L is its length. A minimum weight of 1,000 lb (454 kg) and minimum log stiffness of 350 kip/in. (61,300 kN/m) shall be assumed.

Table 6.11-1. Dynamic Response Ratio for Impulsive Loads, R_{max}.

Ratio of Impact Duration to Natural Period of the Impacted Structural Element	R_{max} (Response Ratio)
0.0	0.0
0.1	0.4
0.2	0.8
0.3	1.1
0.4	1.4
0.5	1.5
0.6	1.7
0.7	1.8
0.9	1.8
1.0	1.7
1.1	1.7
1.2	1.6
1.3	1.6
≥1.4	1.5

The impulse duration for elastic impact shall be calculated from Equation (6.11-4):

$$t_d = \frac{2 m_d u_{max}}{F_{ni}} \quad (6.11\text{-}4)$$

For an equivalent elastic static analysis, the impact force shall be multiplied by the dynamic response factor, R_{max}, specified in Table 6.11-1. To obtain intermediate values of R_{max}, linear interpolation shall be used. For a wall, the impact shall be assumed to act along the horizontal center of the wall, and the natural period shall be permitted to be determined based on the fundamental period of an equivalent column with width equal to one-half of the vertical span of the wall. It also shall be allowed to use an alternative method of analysis per Section 6.11.8.

6.11.3 Impact by Vehicles An impact of floating vehicles shall be applied to vertical structural element(s) at any point greater than 3 ft (0.914 m) above grade up to the maximum depth. The impact force shall be taken as 30 kip (130 kN) multiplied by I_{tsu}.

6.11.4 Impact by Submerged Tumbling Boulder and Concrete Debris Where the maximum inundation depth exceeds 6 ft (1.83 m), an impact force of 8,000 lb (36 kN) multiplied by I_{tsu} shall be applied to vertical structural element(s) at 2 ft (0.61 m) above grade.

6.11.5 Site Hazard Assessment for Shipping Containers, Ships, and Barges Shipping containers and ships or barges dispersed from container yards, ports, and harbors shall be evaluated as potential debris impact objects. In such cases, a probable dispersion region shall be identified for each source to determine if the structure is located within a debris impact hazard region, as defined by the procedure in this section. If the structure is within the debris impact hazard region, then impact by shipping containers and/or ships and barges, as appropriate, shall be evaluated per Sections 6.11.6 and 6.11.7.

6.11.5.1 Debris Impact Hazard Region The debris impact hazard region shall be determined in accordance with this section. The geographic center of the debris source shall be identified, together with the primary flow direction, as defined in Section 6.8.6.1. A line shall be drawn through the source center and perpendicular to the primary flow direction with a length equal to the projected width of the debris source. From the ends of this projected width line, lines shall be drawn at ±22.5 degrees with respect to the direction of tsunami inflow until they reach the grounding limit, as shown in Figure 6.11-1. If topography (such as hills) will bound the water from this sector, the direction of the sector shall be rotated to accommodate hill lines or the wedge shall be narrowed where it is constrained on two or more sides. Where a site-specific inundation analysis spatially defines the topographic diversion of the direction of inundation flow across the Tsunami Design Zone, the primary flow direction shall be permitted to follow the site-specific inundation flow field vectors from the site to the grounding limit, while including 22.5-degree lateral spreading from the predominant flow field vectors.

The inland extent of the debris hazard region shall be curtailed in accordance with the following:

(a) Where the maximum inundation depth is less than 3 ft (0.914 m), or in the case of ships, where the inundation depth is less than the ballasted draft plus 2 ft (0.61 m).
(b) Where structural steel, reinforced concrete, or reinforced solid grouted masonry wall structures act as effective barriers to debris transport. To be considered an effective

@seismicisolation

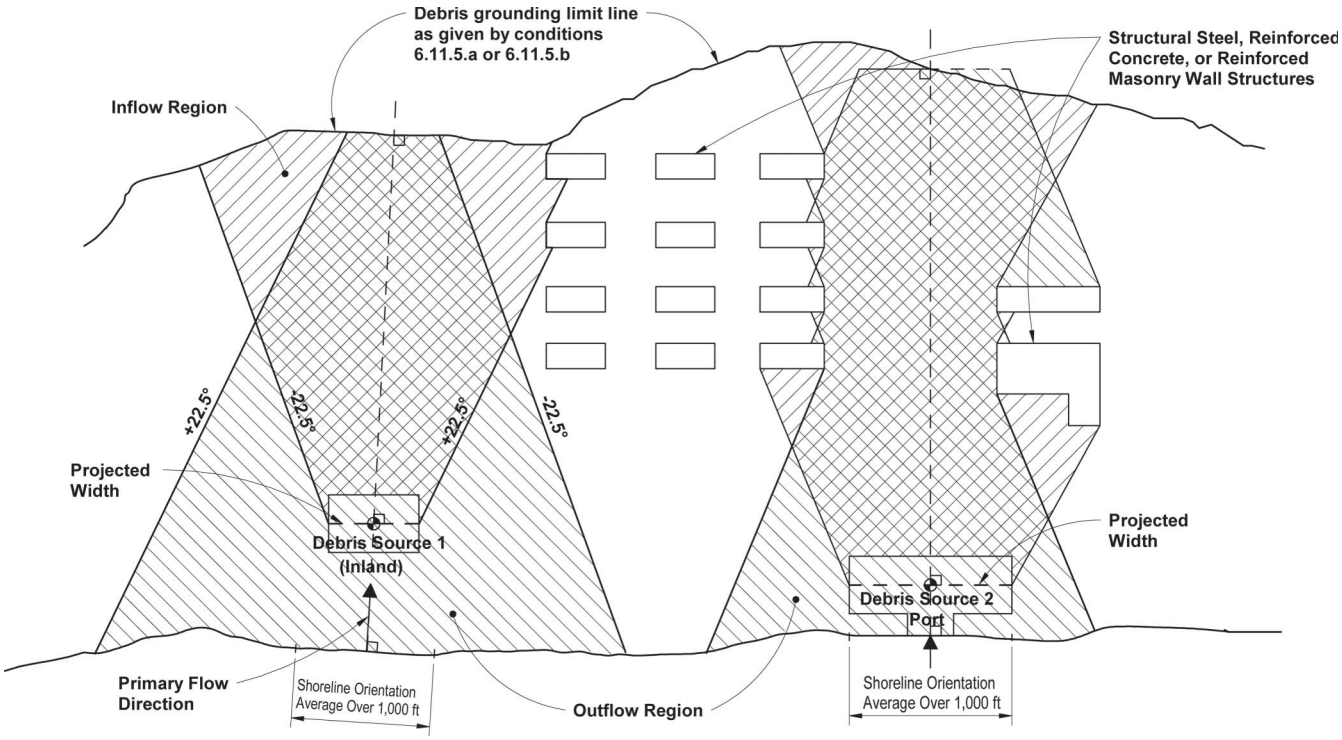

Figure 6.11-1. Illustration of determination of floating debris impact hazard region.
Note: **1 ft = 0.3048 m**.

barrier, the height of these structures shall be at least equal to (1) for containers and barges, the inundation depth minus 2 ft (0.61 m), or (2) for ships, the inundation depth minus the sum of the ballasted draft and 2 ft (0.61 m).

(c) Numerical debris transport modeling shall be permitted to determine the inland extent of the debris impact hazard region, using massless tracers with grounding limit parameters set in accordance with condition 6.11.5.1(a), to represent debris transported by the fluid as provided by a site-specific inundation analysis. Debris transport modeling shall be subject to an independent peer review by a qualified tsunami modeler approved by the Authority Having Jurisdiction, who shall present a written report indicating the scope of their review and their findings to the Authority Having Jurisdiction. Debris impact speeds for design are subject to the minimum flow speeds determined using the procedures of Section 6.6 in accordance with the percentages given in Section 6.7.6.8.

The debris impact hazard region for outflow shall be determined by drawing a line perpendicular to the centerline of the inward flow at the grounding limit line. The line shall be equal in width to the projected width of the source. At each end of this projected width, lines shall be drawn outward at 22.5 degrees from the outflow direction, as shown in Figure 6.11-1. Buildings and other structures contained only in the first sector shall be designed for strikes by a container and/or other vessel carried with the inflow. Buildings and other structures contained only in the second sector shall be designed for strikes by a container and/or other vessel carried in the outflow. Buildings and other structures contained in both sectors shall be designed for strikes by a container and/or other vessel moving in either direction.

6.11.6 Shipping Containers The impact force from shipping containers shall be calculated from Equations (6.11-2) and (6.11-3). The mass m_d is the mass of the empty shipping container. It shall be assumed that the strike contact is from one bottom corner of the front (or rear) of the container. The container stiffness is $k = EA/L$, in which E is the modulus of elasticity of the bottom rail of the container, A is the cross-sectional area of the bottom rail, and L is the length of the bottom rail of the container. Minimum values are provided in Table 6.11-2. C_o, the orientation factor, shall be taken as equal to 0.65 for shipping containers.

The nominal design impact force, F_{ni}, from Equation (6.11-2) for shipping containers need not be taken as greater than 220 kips (980 kN).

For empty shipping containers, the impulse duration for elastic impact shall be calculated from Equation (6.11-4).

For loaded shipping containers the duration of the pulse is determined from Equation (6.11-5):

$$t_d = \frac{(m_d + m_{\text{contents}})u_{\max}}{F_{ni}} \tag{6.11-5}$$

in which m_{contents} shall be taken to be 50% of the maximum rated content capacity of the shipping container. Minimum values of $(m_d + m_{\text{contents}})$ are given in Table 6.11-2 for loaded shipping containers. The design shall consider both empty and loaded shipping containers.

For an equivalent static analysis, the impact force shall be multiplied by the dynamic response factor, $R_{\max}$, specified in Table 6.11-1. To obtain intermediate values of $R_{\max}$, linear interpolation shall be used. For a wall, the impact shall be assumed to act along the horizontal center of the wall, and the natural period shall be permitted to be determined based on the

@seismicisolation

Table 6.11-2. Weight and Stiffness of Shipping Container Waterborne Floating Debris.

Type of Debris	Weight	Debris Stiffness (k)
20 ft (6.1 m) standard shipping container oriented longitudinally	Empty: 5,000 lb (2,270 kg) Loaded: 29,000 lb (13,150 kg)	245 kip/in. (42,900 kN/m)
40 ft (12.19 m) standard shipping container oriented longitudinally	Empty: 8,400 lb (3,810 kg) Loaded: 38,000 lb (17,240 kg)	170 kip/in. (29,800 kN/m)

period of an equivalent column with width equal to one-half of the vertical span of the wall.

It also shall be permitted to use an alternative method of analysis per Section 6.11.8.

6.11.7 Extraordinary Debris Impacts Where the maximum inundation depth exceeds 12 ft (3.66 m), extraordinary debris impacts of the largest deadweight tonnage vessel with ballasted draft less than the inundation depth within the debris hazard region of piers and wharves defined in Section 6.11.5 shall be assumed to impact the perimeter of Tsunami Risk Category III Critical Facilities and Tsunami Risk Category IV buildings and structures anywhere from the base of the structure up to 1.3 times the inundation depth plus the height to the deck of the vessel. The load shall be calculated from Equation (6.11-3), based on the stiffness of the impacted structural element and a weight equal to the Lightship Weight (LWT) plus 30% of Deadweight Tonnage (DWT). An alternative analysis of Section 6.11.8 shall be permitted. Either as the primary approach, or where the impact loads exceed acceptability criteria for any structural element subject to impact, it is permitted to accommodate the impact through the alternative load path progressive collapse provisions of Section 6.8.3.5.3, applied to all framing levels from the base up to the story level above 1.3 times the inundation depth plus the height to the deck of the vessel as measured from the waterline.

6.11.8 Alternative Methods of Response Analysis A dynamic analysis is permitted to be used to determine the structural response to the force applied as a rectangular pulse of duration time, t_d, with the magnitude calculated in accordance with Equation (6.11-3). If the impact is large enough to cause inelastic behavior in the structure, it shall be permitted to use an equivalent single degree of freedom mass-spring system with a nonlinear stiffness that considers the ductility of the impacted structure for the dynamic analysis. Alternatively, for inelastic impact, the structural response shall be permitted to be calculated based on a work-energy method with nonlinear stiffness that incorporates the ductility of the impacted structure. The velocity applied in the work-energy method of analysis shall be u_{max} multiplied by the product of Importance Factor, I_{tsu}, and the orientation factor, C_o.

6.12 FOUNDATION DESIGN

Design of structure foundations and tsunami barriers shall provide resistance to the loads and effects of Section 6.12.2, shall provide capacity to support the structural load combinations defined in Section 6.8.3.1, and shall accommodate the displacements determined in accordance with Section 6.12.2.6. Foundation embedment depth and the capacity of the exposed piles to resist structural loads, including grade beam loads, shall both be determined taking into account the cumulative effects of general erosion and local scour. Alternatively, it shall be permitted to use the performance-based criteria of Section 6.12.3.

Site characterization shall include relevant information specified in Section 11.8, Geotechnical Investigation Report Requirements for Subsurface Soil Conditions.

6.12.1 Resistance Factors for Foundation Stability Analyses The resistance factor of φ shall be assigned a value of 0.67 applied to the resisting capacities for use with stability analyses and for potential failures associated with bearing capacity, lateral pressure, internal stability of geotextile and reinforced earth systems, and slope stability, including drawdown conditions. A resistance factor of 0.67 shall also be assigned for the resisting capacities of uplift-resisting anchorage elements.

6.12.2 Load and Effect Characterization Foundations and tsunami barriers shall be designed to accommodate the effects of lateral earth pressure in accordance with Section 3.2, hydrostatic forces computed in accordance with Section 6.9, hydrodynamic loads computed in accordance with Section 6.10, and uplift and underseepage forces computed in accordance with Section 6.12.2.1. Foundations shall provide the capacity to withstand uplift and overturning from tsunami hydrostatic, hydrodynamic, and debris loads applied to the building superstructure. In addition, the effect of soil strength loss, general erosion, and scour shall be considered in accordance with the requirements of this section. A minimum of two wave cycles shall be considered for such effects.

6.12.2.1 Uplift and Underseepage Forces Tsunami uplift and underseepage forces shall be evaluated as described in this section.

1. Uplift and underseepage forces shall include the three inundation Load Cases defined in Section 6.8.3.1.
2. Uplift and underseepage forces on the foundation shall be determined for cases where
   (a) The soil is expected to be saturated before the tsunami, or
   (b) Soil saturation is anticipated to occur over the course of the incoming series of tsunami waves, or
   (c) The area of concern is expected to remain inundated after the tsunami.
3. The effect of live load and snow load shall not be used for uplift resistance.

6.12.2.2 Loss of Strength The effects of the loss of soil shear strength on erosion and scour shall be considered in accordance with Sections 6.12.2.3 and 6.12.2.4, respectively, and foundations shall be designed to accommodate loss of soil shear strength through tsunami-induced pore pressure softening when

1. The maximum Froude number at the site is 0.5 or greater, and
2. Figure 6.12-2 indicates that the pore pressure softening parameter at the ground surface, $\Lambda_T(0)$, is 0.5 or greater.

@seismicisolation

$\Lambda_T(0)$ shall be determined in accordance with Equation 6.12-1:

$$\Lambda_T(0) = \min\left[1, \frac{2F_\Lambda}{\sqrt{\pi I_\Lambda}}\right] \quad (6.12\text{-}1)$$

where

F_Λ = Pore pressure softening vertical flux index, shall be determined in accordance with Equation (6.12-2):

$$F_\Lambda = \frac{\gamma_s}{\gamma_b}(1-\kappa_d)h_{draw} \quad (6.12\text{-}2)$$

I_Λ = Pore pressure softening drawdown inertia index, shall be determined in accordance with Equation (6.12-3):

$$I_\Lambda = c_v \cdot T_{draw} \quad (6.12\text{-}3)$$

γ_b = Buoyant weight density of the soil, assuming the pore water is clean sea water with specific weight density equal to γ_{sw};
γ_s = Fluid weight density for tsunami loads per Equation (6.8-4);
h_{draw} = Difference between the maximum inundation depth and the residual water level after drawdown of the associated wave, as shown in Figure 6.12-1. Where a site-specific time series inundation analysis is not available, h_{draw} shall be taken as the maximum inundation depth, h_{max}, determined per Section 6.6.2;
T_{draw} = Site-specific drawdown timescale as defined per Figure 6.12-1. Where a site-specific time series inundation analysis is not available, T_{draw} shall be taken as one-quarter of the predominant wave period, T_{TSU};
c_v = Coefficient of consolidation in ft^2/s (m^2/s); and
κ_d = Drainage factor, determined from Table 6.12-1. If variable soil conditions are present, it shall be permitted to use $\kappa_d = 0.2$.

The minimum depth of soil shear strength loss through tsunami-induced pore pressure softening shall be the lesser of:

1. A depth of 1.2 times h_{draw}, or
2. The susceptible depth, D_e, as determined from Figure 6.12-3.

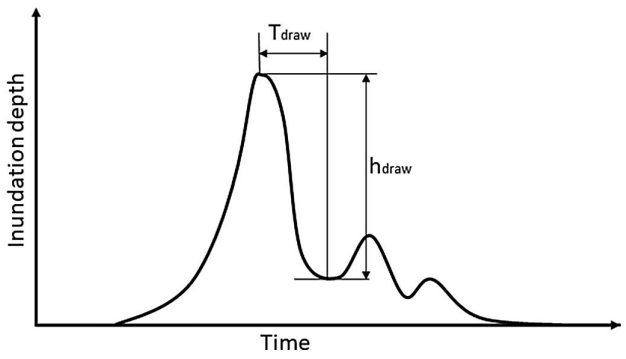

Figure 6.12-1. Site-specific tsunami inundation wave parameters used for pore pressure softening evaluation.

Table 6.12-1. Drainage Factor, κ_d, for Different Soil Types.

Soil Type	κ_d
Very soft to soft clay	0.3
Medium stiff clay	0.2
Stiff clay	0.1
Loose sand	0.3
Dense sand	0.1
Very dense sand and gravel, sandy clay, or silty sand	0.05

EXCEPTION: The depth of soil shear strength loss shall not extend below the depth where bedrock is encountered.

The softened soil shear strength shall be determined by multiplying the unsoftened soil shear strength by a factor of $(1-\Lambda_T)$, where Λ_T is determined by Equation (6.12-1). This reduction of strength shall be permitted to be applied uniformly throughout the susceptible depth, D_e, or varied linearly using $\Lambda_T = \Lambda_T(0)$ at the ground surface and $\Lambda_T = 0.5$ at D_e. Alternatively, the magnitude and distribution of the loss of strength shall be determined by physical or numerical modeling of soil–structure–fluid interactions.

6.12.2.3 General Erosion General erosion during tsunami inundation runup and drawdown conditions shall be considered. Analysis of general erosion shall account for flow amplification as described in Section 6.8.5 and soil strength loss as described in Section 6.12.2.2.

EXCEPTION: Analysis of general erosion is not required for rock or other nonerodible strata that are capable of preventing erosion due to tsunami flow velocities of 30 ft/s (9.14 m/s).

General erosion during drawdown conditions shall consider flow concentration in channels, including channels newly formed during tsunami inundation and drawdown (channelized scour). Analysis of erosion due to channelized scour need not include enhancement caused by pore pressure softening.

6.12.2.4 Scour The depth and extent of scour adjacent to foundation elements shall be evaluated using the methods of Sections 6.12.2.4.1 and 6.12.2.4.2. Analysis of scour shall take into account tsunami flow cycles as described in Section 6.8.8 and loss of strength as described in Section 6.12.2.2.

EXCEPTION: Scour evaluation is not required for rock or other nonerodible strata that are capable of preventing scour from tsunami flow velocities of 30 ft/s (9.14 m/s) nor for open structures.

6.12.2.4.1 Sustained Flow Scour Scour, including the effects of sustained flow around structures, shall be evaluated at the foundations of building corners and at the extreme ends of structural piers or walls within 22.5 degrees of perpendicular to the flow and having a projected width to maximum inundation depth ratio of 3 or more. Calculated sustained flow scour depth shall be taken to be at the flow-facing surface of the foundation element. The assumed spatial extent shall be considered to encompass the indicated building perimeter elements and to extend from those foundation elements at a 1 vertical to 1 horizontal slope for consolidated or cohesive soils and at a 1 vertical to 3 horizontal slope for unconsolidated or granular soils. Scour depth need not be taken lower than the top surface of intact rock strata or other nonerodible strata that are capable of preventing scour from tsunami flow of 30 ft/s (9.14 m/s), nor be determined for open structures. Sustained flow scour design depth and extent shall be determined by one of the following methods:

@seismicisolation

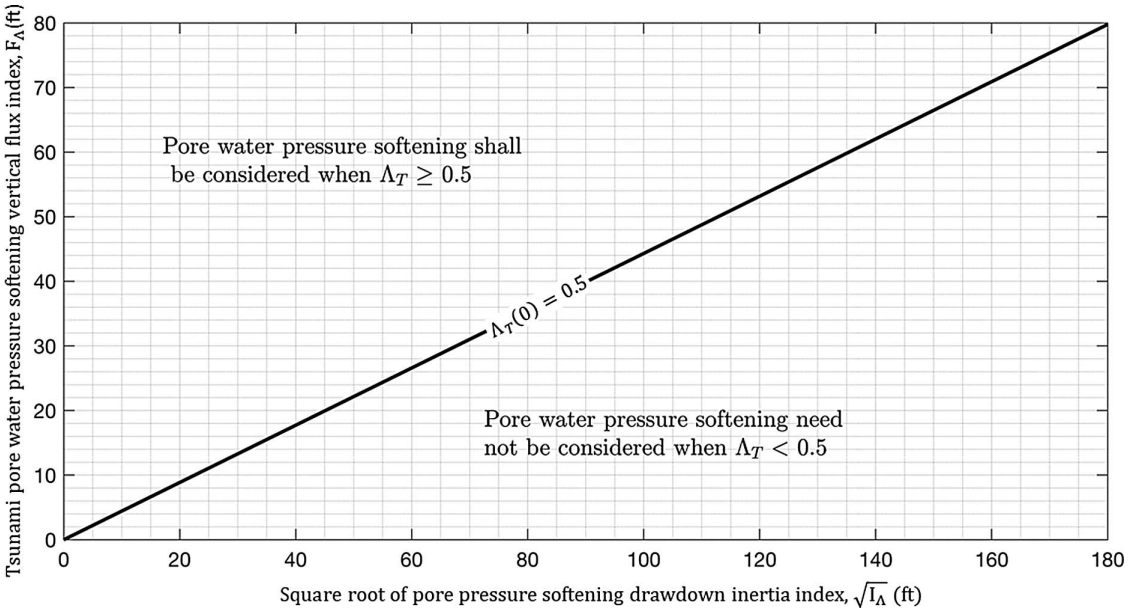

Figure 6.12-2. Susceptibility to pore pressure softening due to tsunami inundation.
Note: 1 ft = 0.305 m.

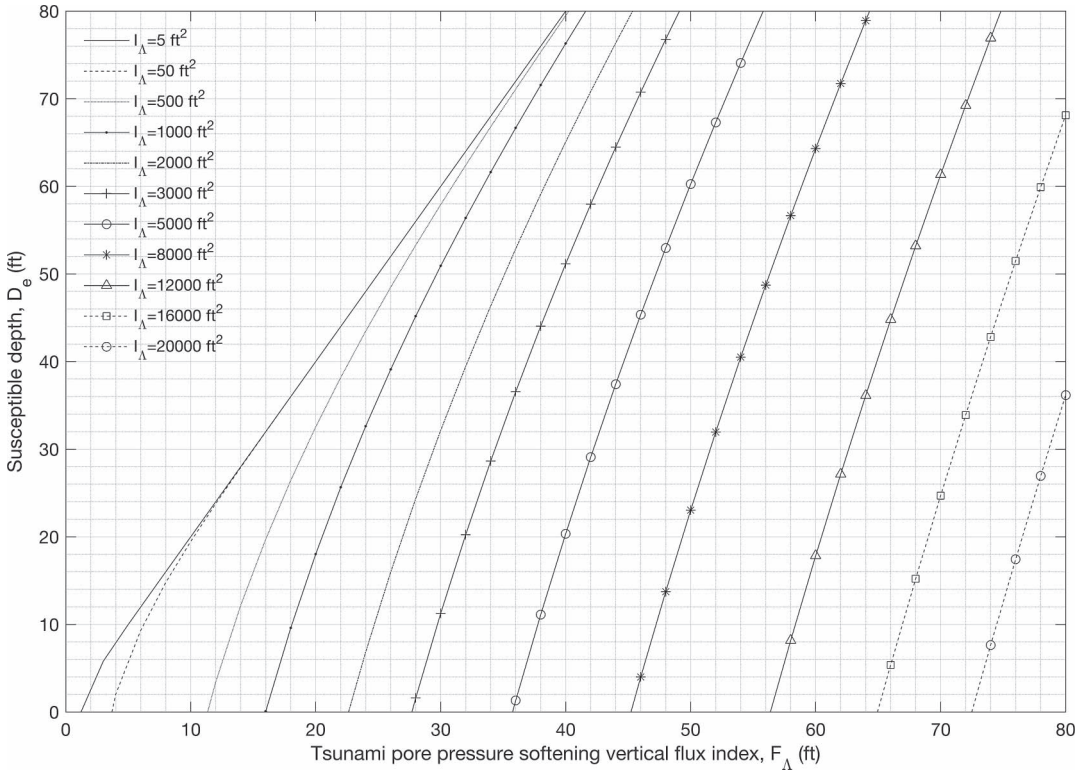

Figure 6.12-3. Susceptible depth, D_e, affected by tsunami-induced pore pressure softening
Note: 1 ft = 0.305 m; 1 ft^2 = 0.093 m^2.

(a) Dynamic numerical or physical modeling or empirical methods in the recognized literature.
(b) Sustained flow scour with associated pore pressure softening effects determined in accordance with Table 6.12-2 and Figure 6.12-4. Local scour depth caused by sustained flow given by Table 6.12-2 and Figure 6.12-4 shall be permitted to be reduced by an adjustment factor in areas where the maximum flow Froude number determined in accordance with Equation (6.6-3) is less than 0.5. The adjustment factor shall be taken as varying linearly from 0 at the horizontal inundation limit to 1.0 at the point where the Froude number is 0.5.

@seismicisolation

Table 6.12-2. Design Scour Depth Caused by Sustained Flow and Pore Pressure Softening.

Inundation Depth, h	Scour Depth, D^*
<10 ft (3.05 m)	$1.2h$
≥10 ft (3.05 m)	12 ft (3.66 m)

*Not applicable to scour at sites with intact rock strata.

Table 6.12-3. Vertical Extent of Pile Scour to Projected Element Width Ratio, D_s/b.

Froude Number, F_r	D_s/b
<1.0	$1.3F_r$
≥1.0	1.3

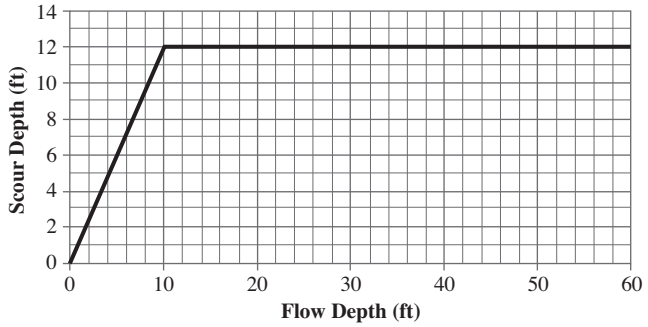

Figure 6.12-4. Scour depth caused by sustained flow and pore pressure softening.

Note: 1 ft = 0.305 m.

(c) Where vertical foundation elements, with cross sections not exceeding an aspect ratio of 2:1, become exposed to flow through local scour determined in accordance with method (a) or (b), or through general erosion as determined in accordance with Section 6.12.2.3, and where the Froude number is less than 1.7, it shall be permitted to calculate the vertical extent of pile scour along the length of the vertical foundation element using Table 6.12-3 and Figure 6.12-5. The width, b, is the projected foundation element width in the direction perpendicular to the flow. The total scour for the foundation need not exceed the depth determined by Figure 6.12-4.

6.12.2.4.2 Plunging Scour Plunging scour horizontal extent and depth shall be determined by dynamic numerical or physical modeling or by empirical methods. In the absence of site-specific dynamic modeling and analysis, the plunging scour depth, D_s shall be determined by Equation (6.12-4).

$$D_s = c_{2V}\sqrt{\frac{qU\sin\psi}{g}}\text{[U.S.standard or SI units]} \qquad (6.12\text{-}4)$$

where

c_{2V} = Dimensionless scour coefficient, permitted to be taken as equal to 2.8;

ψ = Angle between the jet at the scour hole and the horizontal, taken as the lesser value of 75 degrees and the side slope of the overtopped structure on the scoured side, in the absence of other information;

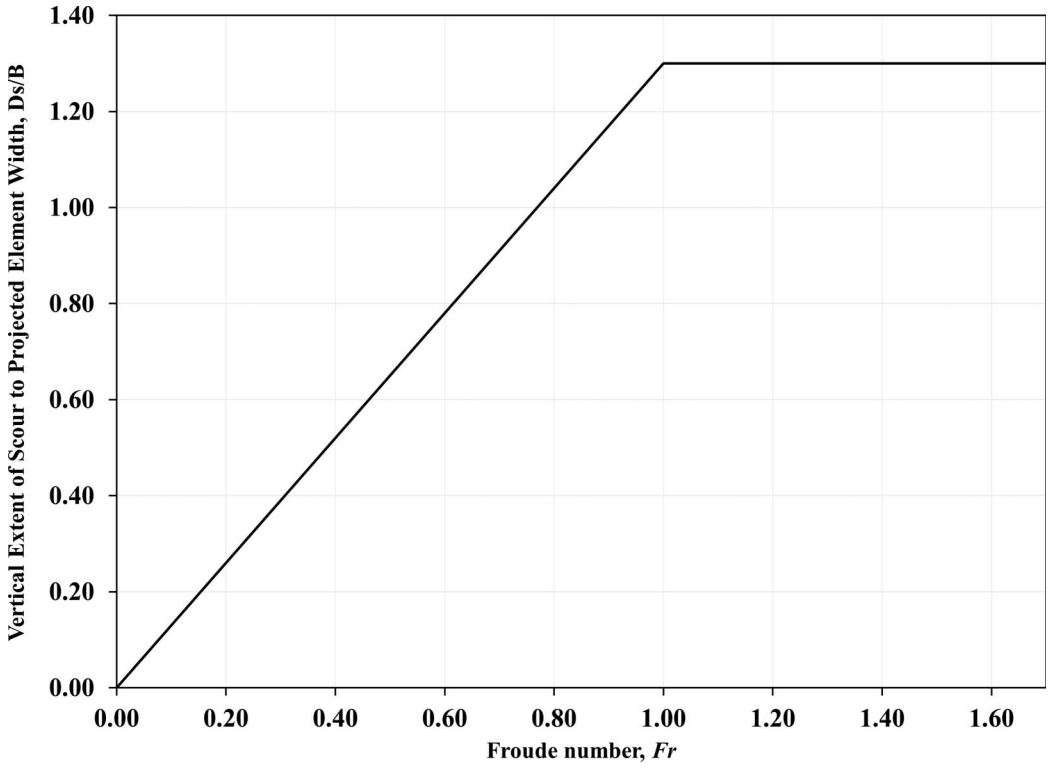

Figure 6.12-5. Vertical extent of pile scour to projected element width ratio.

@seismicisolation

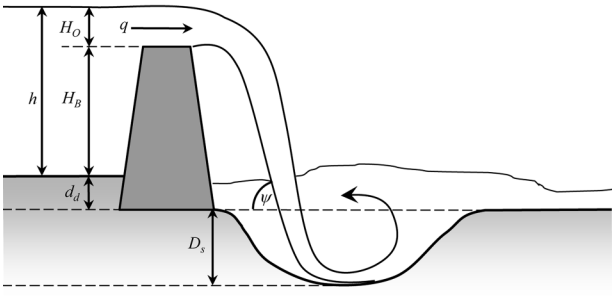

Figure 6.12-6. Plunging scour parameters.

g = Acceleration caused by gravity;
q = Discharge per unit width over the overtopped structure, as illustrated in Figure 6.12-6 and calculated in accordance with Equation (6.12-5); and
U = Jet velocity approaching the scour hole, obtained in accordance with Equation (6.12-7).

$$q = C_{dis}\frac{2}{3}\sqrt{2g}H_O^{3/2} \tag{6.12-5}$$

where C_{dis} is a dimensionless discharge coefficient obtained in accordance with Equation (6.12-3):

$$C_{dis} = 0.611 + 0.08\frac{H_O}{H_B} \tag{6.12-6}$$

U is the jet velocity approaching the scour hole, resulting from the drop between the height h of the upstream water surface, plus any additional elevation difference d_d on the scouring side, in accordance with Equation (6.12-7):

$$U = \sqrt{2g(h + d_d)} \tag{6.12-7}$$

where d_d is the additional elevation difference between the upstream and scouring sides of the structure, as illustrated in Figure 6.12-3.

6.12.2.5 Horizontal Soil Loads Horizontal soil loads caused by unbalanced scour shall be included in the design of foundation elements.

6.12.2.6 Displacements Vertical and horizontal displacements of foundation elements and slope displacements shall be determined using empirical or elastoplastic analytical or numerical methods in the recognized literature by applying tsunami loads determined in Section 6.12.2 together with other applicable geotechnical and foundation loads required by this standard.

6.12.3 Alternative Foundation Performance-Based Design Criteria In situ soil stresses from tsunami loads and effects shall be included in the calculation of foundation pressures. For local coseismic tsunami hazards that occur as a result of a local earthquake, the in situ soil and site surface condition at the onset of tsunami loads shall be those existing at the end of seismic shaking, including liquefaction, lateral spread, and fault rupture effects.

Building foundations shall provide sufficient capacity and stability to resist structural loads and the effects of general erosion and scour in accordance with the recognized literature. For Tsunami Risk Category IV buildings and structures, it shall be permitted to evaluate the overall performance of the foundation system for potential pore pressure softening by performing a two- or three-dimensional tsunami–soil–structure interaction numerical modeling analysis. The results shall be evaluated to demonstrate consistency with the structural performance acceptance criteria in Section 6.8. For Tsunami Risk Category IV buildings and structures, an independent peer review shall be conducted as part of a review of the performance-based design by the Authority Having Jurisdiction.

6.12.4 Foundation Countermeasures Fill, protective slab on grade, geotextiles and reinforced earth systems, facing systems, and ground improvement shall be permitted to reduce the effects of tsunamis.

6.12.4.1 Fill Fill used for structural support and protection shall be placed in accordance with ASCE 24, Sections 1.5.4 and 2.4.1. Structural fill shall be designed to be stable during inundation and to resist the loads and effects specified in Section 6.12.2.

6.12.4.2 Protective Slab on Grade Exterior slabs on grade shall be assumed to be uplifted and displaced during the Maximum Considered Tsunami unless determined otherwise by site-specific design analysis based upon recognized literature. Protective slabs on grade used as a countermeasure shall at a minimum have the strength necessary to resist the following loads:

1. Shear forces from sustained flow at maximum tsunami flow velocity, u_{max}, over the slab on grade;
2. Uplift pressures from flow acceleration at upstream and downstream slab edges for both inflow and return flow;
3. Seepage flow gradients under the slab if the potential exists for soil saturation during successive tsunami waves;
4. Pressure fluctuations over slab sections and at joints;
5. Pore pressure increases from liquefaction and from the passage of several tsunami waves; and
6. Erosion of substrate at upstream, downstream, and flow parallel slab edges, as well as between slab sections.

6.12.4.3 Geotextiles and Reinforced Earth Systems Geotextiles shall be designed and installed in accordance with manufacturers' installation requirements and as recommended in the recognized literature. Resistance factors required in Section 6.12.1 shall be provided for bearing capacity, uplift, lateral pressure, internal stability, and slope stability.

The following reinforced earth systems shall be permitted to be used:

1. Geotextile tubes constructed of high-strength fabrics capable of achieving full tensile strength without constricting deformations when subject to the design tsunami loads and effects;
2. Geogrid earth and slope reinforcement systems that include adequate protection against general erosion and scour, and a maximum lift thickness of 1 ft (0.3 m) and facing protection; and
3. Geocell earth and slope reinforcement erosion protection system designs, including an analysis to determine anticipated performance against general erosion and scour if no facing is used.

6.12.4.4 Facing Systems Facing systems and their anchorage shall be sufficiently strong to resist uplift and displacement during design load inundation. The following facing methods for reinforced earth systems shall be permitted to be used:

@seismicisolation

1. Vegetative facing for general erosion and scour resistance where tsunami flow velocities are less than 12.5 ft/s (3.81 m/s). Design shall be in accordance with methods and requirements in the recognized literature.
2. Geotextile filter layers, including primary filter protection of countermeasures using a composite grid assuming high contact stresses and high-energy wave action design criteria in AASHTO M288-06, including soil retention, permeability, clogging resistance, and survivability.
3. Mattresses providing adequate flexibility and including energy dissipation characteristics. Edges shall be embedded to maintain edge stability under design inundation flows.
4. Concrete facing provided in accordance with protective slab-on-grade countermeasures in Section 6.12.4.2 and containing adequate anchorage to the reinforced earth system under design inundation flows.
5. Stone armoring and riprap provided to withstand tsunami shall be designed as follows: Stone diameter shall not be less than the size determined based on tsunami inundation depth and currents using design criteria in the recognized literature. Where the maximum Froude number, F_r, is 0.5 or greater, the high-velocity turbulent flows associated with tsunamis shall be specifically considered, using methods in the recognized literature.

Subject to independent review, it shall be permitted to base designs on physical or numerical modeling.

6.12.4.5 Ground Improvement Ground improvement countermeasures shall be designed using soil–cement mixing to provide nonerodible scour protection per Section 6.12.2.4 and at minimum provide soil–cement mass strength reinforcement of 100 psi (0.69 MPa) average unconfined compressive strength.

6.13 STRUCTURAL COUNTERMEASURES FOR TSUNAMI LOADING

The following countermeasures shall be permitted to reduce the structural effects of tsunamis.

6.13.1 Open Structures Open Structures shall not be subject to Load Case 1 of Section 6.8.3.1. The load effect of debris accumulation against or within the Open Structure shall be evaluated by assuming a minimum closure ratio of 50% of the Innundated Projected Area along the perimeter of the Open Structure.

6.13.2 Tsunami Barriers Tsunami barriers used as an external perimeter structural countermeasure shall be designed consistent with the protected structure performance objectives to jointly achieve the performance criteria. These criteria include barrier strength, stability, slope erosion protection, toe scour, and geotechnical stability requirements and barrier height and footprint to fully prevent inundation during the Maximum Considered Tsunami. Where a barrier is designed to be overtopped by the design event or intended to provide only partial impedance of the design event, the protected structure and its foundation shall be designed for the residual inundation resulting from the design event. The foundation system treatment requirements in Section 6.12 of this chapter shall also be applied.

6.13.2.1 Information on Existing Buildings and Other Structures to Be Protected As-built information on building configuration, building components, site, and foundation shall be permitted to be evaluated in accordance with ASCE 41, Chapters 9 through 11.

6.13.2.2 Site Layout The spatial limits of the layout of tsunami barriers shall include the following:

1. The tsunami barrier shall be set back from the protected structure for perimeter protection. Any alignment change shall have a minimum radius of curvature equal to at least half the maximum inundation depth.
2. For overtopping or partial impedance to inundation, at a minimum the barrier limits shall protect the structure from inundation flow based on an approach angle of ±22.5 degrees from the shoreline. The flow approach angle shall be evaluated in accordance with Sections 6.8.6.1 and 6.8.6.2.

6.14 TSUNAMI VERTICAL EVACUATION REFUGE STRUCTURES

Tsunami Vertical Evacuation Refuge Structures designated as a means of alternative evacuation by the Authority Having Jurisdiction shall be designed in accordance with the additional requirements of this section.

6.14.1 Minimum Inundation Elevation and Depth Tsunami refuge floors shall be located not less than the greater of 10 ft (3.0 m) or one-story height above 1.3 times the Maximum Considered Tsunami inundation elevation at the site as determined by a site-specific inundation analysis, as indicated in Figure 6.14-1. This same Maximum Considered Tsunami

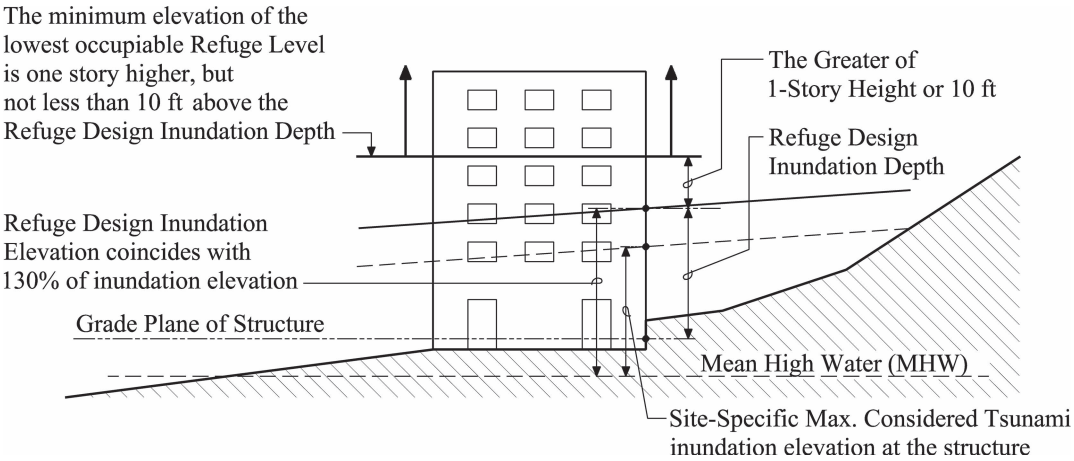

Figure 6.14-1. Minimum refuge level elevation (1 ft = 0.305 m).

@seismicisolation

site-specific inundation elevation, factored by 1.3, shall also be used for design of the Tsunami Vertical Evacuation Refuge Structure in accordance with Sections 6.8 to 6.12. The 1.3 factor is not applicable to relative sea level change and regional seismic subsidence.

6.14.2 Refuge Live Load An assembly live load, L_{refuge}, of 100 lb/ft^2 (4.8 kPa) shall be used in any designated evacuation floor area within a tsunami refuge floor level.

6.14.3 Laydown Impacts Where the maximum inundation depth exceeds 6 ft (1.83 m), the laydown impact of adjacent pole structures collapsing onto occupied portions of the building shall be considered.

6.14.4 Information on Construction Documents Construction documents shall include tsunami design criteria and the occupancy capacity of the tsunami refuge area. Floor plans shall indicate all refuge areas of the facility and exiting routes from each area. The latitude and longitude coordinates of the building shall be recorded on the construction documents.

6.14.5 Peer Review Design shall be subject to independent peer review by an appropriately licensed design professional, who shall present a written report to the Authority Having Jurisdiction as to the design's compliance with the requirements of this standard.

6.15 DESIGNATED NONSTRUCTURAL COMPONENTS AND SYSTEMS

6.15.1 Performance Requirements Designated nonstructural components and systems in structures located in the Tsunami Design Zone shall be either protected from tsunami inundation effects or positioned in the structure above the inundation elevation of the Maximum Considered Tsunami, such that the designated nonstructural components and systems will be capable of performing their critical function during and after the Maximum Considered Tsunami. Tsunami barriers used as inundation protection shall have a top-of-wall elevation that is not less than 1.3 times the maximum inundation elevation at the barrier. The 1.3 factor is not applicable to relative sea level change and regional seismic subsidence. The tsunami barrier shall also satisfy the requirements of Section 6.13. Alternatively, it shall be permitted to design the designated nonstructural components and systems directly for tsunami effects, provided that inundation would not inhibit them from performing their critical function during and after the Maximum Considered Tsunami.

6.16 NONBUILDING TSUNAMI RISK CATEGORY III AND IV STRUCTURES

6.16.1 Requirements for Tsunami Risk Category III Nonbuilding Structures Tsunami Risk Category III nonbuilding structures located in the Tsunami Design Zone shall be either protected from tsunami inundation effects or designed to withstand the effects of tsunami loads in accordance with Section 6.8 of this chapter and in accordance with the specific performance requirements of Section 6.8.3. Tsunami barriers used as inundation protection shall have a top-of-wall elevation that is not less than 1.3 times the maximum inundation elevation at the barrier. The 1.3 factor is not applicable to relative sea level change and regional seismic subsidence. The tsunami barrier shall also satisfy the requirements of Section 6.13.

6.16.2 Requirements for Tsunami Risk Category IV Nonbuilding Structures Tsunami Risk Category IV designated nonstructural systems in nonbuilding structures located in the Tsunami Design Zone shall be (1) protected from tsunami inundation effects, (2) positioned above 1.3 times the inundation elevation of the Maximum Considered Tsunami in such a manner that the Tsunami Risk Category IV nonbuilding structure will be capable of performing its critical function during and after the Maximum Considered Tsunami, or (3) designed to withstand the effects of tsunami loads in accordance with Section 6.8 of this chapter and the specific performance requirements of Section 6.8.3. Tsunami barriers used as inundation protection shall have a top-of-wall elevation that is not less than 1.3 times the maximum inundation elevation at the barrier. The 1.3 factor is not applicable to relative sea level change and regional seismic subsidence. The tsunami barrier shall also satisfy the requirements of Section 6.13.

6.17 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

This section lists the consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter. Those referenced documents identified by an asterisk (*) are not consensus standards; rather, they are documents developed within the industry and represent acceptable procedures for design and construction to the extent referred to in the specified section.

CHAPTER 7
SNOW LOADS

7.1 DEFINITIONS AND SYMBOLS

7.1.1 Definitions

ASCE DESIGN GROUND SNOW LOAD GEODATABASE: The ASCE database (version 2022-1.0) of geocoded values of risk-targeted design ground snow load values.

DRIFT: The accumulation of wind-driven snow that results in a local surcharge load on the roof structure at locations such as a parapet or roof step.

FLAT ROOF SNOW LOAD: Uniform load for flat roofs.

FREEZER BUILDINGS: Buildings in which the inside temperature is kept at or below freezing. Buildings with an air space between the roof insulation layer above and a ceiling of the freezer area below are not considered freezer buildings.

GROUND SNOW LOAD: The site-specific weight of the accumulated snow at the ground level used to develop roof snow loads on the structure.

MINIMUM SNOW LOAD: Snow load on low sloped roofs, including the roof snow load immediately after a single snowstorm without wind.

PONDING: Refer to definitions in Chapter 8, "Rain Loads."

PONDING INSTABILITY: Refer to definitions in Chapter 8, "Rain Loads."

R-VALUE: A measure of the resistance to heat flow through a roof component or assembly per unit area.

SLIPPERY SURFACE: Membranes with a smooth surface, for example, glass, metal, or rubber. Membranes with an embedded aggregate or mineral granule surface are not considered a slippery surface.

SLOPED ROOF SNOW LOAD: Uniform load on horizontal projection of a sloped roof, also known as the balanced load.

VENTILATED ROOF: Roof that allows exterior air to naturally circulate between the roof surface above and the insulation layer below. The exterior air commonly flows from the eave to the ridge.

7.1.2 Symbols

C_e = Exposure factor, as determined from Table 7.3-1
C_s = Slope factor, as determined from Figure 7.4-1
C_t = Thermal factor, as determined from Table 7.3-2
h = Vertical separation distance, feet (m), between the edge of a higher roof including any parapet and the edge of a lower adjacent roof excluding any parapet
h_b = Height of balanced snow load, determined by dividing p_s by γ, ft (m)
h_c = Clear height from top of balanced snow load to (1) closest point on adjacent upper roof, (2) top of parapet, or (3) top of a projection on the roof, ft (m)
h_d = Height of snow drift, ft (m)
h_{d1} or h_{d2} = Heights of snow drifts where two intersecting snow drifts can form, ft (m)
h_o = Height of obstruction above the surface of the roof, ft (m)
l_u = Length of the roof upwind of the drift, ft (m)
p_d = Maximum intensity of drift surcharge load, lb/ft^2 (kN/m^2)
p_f = Snow load on flat roofs ("flat" = roof slope $\leq 5°$), lb/ft^2 (kN/m^2)
p_g = Ground snow load, as determined from Figure 7.2-1 and Table 7.2-1; or a site-specific analysis, lb/ft^2 (kN/m^2)
p_m = Minimum snow load for low-slope roofs, lb/ft^2 (kN/m^2)
p_s = Sloped roof (balanced) snow load, lb/ft^2 (kN/m^2)
s = Horizontal separation distance between the edges of two adjacent buildings, ft (m)
S = Roof slope run for a rise of one
w = Width of snow drift, ft (m)
w_1 or w_2 = Widths of snow drifts where two intersecting snow drifts can form, ft (m)
W = Horizontal distance from eave to ridge, ft (m)
W_2 = Percent time wind speed is above 10 mph (4.6 m/s) during winter (October through April); winter wind parameter from Figure 7.6-1 and Table 7.2-1 for Alaska
γ = Snow density, as determined from Equation (7.7-1), lb/ft^3 (kN/m^3)
θ = Roof slope on the leeward side, degrees

7.2 GROUND SNOW LOADS, p_g

Ground snow loads, p_g, to be used in the determination of design snow loads shall be determined using the ASCE Design Ground Snow Load Geodatabase. A graphical representation of the data in the ASCE Design Ground Snow Load Geodatabase is shown in Figures 7.2-1A through 7.2-1D for the conterminous United States and Table 7.2-1 for Alaska. Where the results from the geodatabase indicate that a case study needs to be conducted for a specific location, the ground snow load determination for the location shall be based on an analysis of data available in the vicinity of the site, shall meet the reliability targets set forth in Table 1.3-1, and shall be approved by the Authority Having Jurisdiction.

User Note: The ASCE Design Ground Snow Load Geodatabase of geocoded design ground snow load values for all four risk categories is available at https://asce7hazardtool.online/ or approved equivalent.

Notes: To convert lb/ft^2 to kN/m^2, multiply by 0.0479. To convert feet to meters, multiply by 0.3048.

1. Statutory requirements of the Authority Having Jurisdiction are not included in this state ground snow load table.
2. For locations where there is substantial change in altitude over the city/town, the load applies at and below the cited elevation within the jurisdiction and up to 100 ft above the cited elevation, unless otherwise noted.
3. For locations in Anchorage/Eagle River and Homer above the cited elevation, the ground snow load shall be increased by 15% for every 100 ft above the cited elevation.

@seismicisolation

Snow loads are zero for Hawaii, except in mountainous regions, as determined by the Authority Having Jurisdiction.

EXCEPTION: The snow load provisions of this chapter need not be considered for roofs or roof members with no potential for drift accumulation or unbalanced snow loading where the ground snow load, p_g, is less than the factored roof live load used in design. For all other roofs or roof members, the snow load provisions in this chapter do not need to be considered in either of the following situations:

- The ground snow load, p_g, is less than or equal to 10 lb/ft^2 (0.48 kN/m^2) and the length of the roof upwind from any potential drifting location, l_u, is less than or equal to 100 ft (30.48 m).
- The ground snow load, p_g, is less than or equal to 5 lb/ft^2 (0.24 kN/m^2) and the length of the roof upwind from any potential drifting location, l_u, is less than or equal to 300 ft (91.44 m).

The ground snow load, p_g, shall be used as the balanced snow load for snow accumulation surfaces, such as decks, balconies, and other near-ground level surfaces or roofs of subterranean spaces, whose height above the ground surface is less than the depth of the ground snow, h_g ($h_g = p_g/\gamma$).

7.3 FLAT ROOF SNOW LOADS, p_f

The flat roof snow load, p_f, shall be calculated in lb/ft^2 (kN/m^2) using the following formula:

$$p_f = 0.7 C_e C_t p_g \tag{7.3-1}$$

7.3.1 Exposure Factor, C_e The value for C_e shall be determined from Table 7.3-1.

7.3.2 Thermal Factor, C_t The value for C_t shall be determined from Tables 7.3-2 and 7.3-3.

For values of P_g and R_{roof} that fall between those shown in Table 7.3-3, linear interpolation may be used to determine the value of C_t.

7.3.3 Minimum Snow Load for Low-Slope Roofs, p_m A minimum roof snow load, p_m, shall only apply to monoslope, hip, and gable roofs with slopes less than 15 degrees and to curved roofs where the vertical angle from the eaves to the crown is less than 10 degrees. The minimum roof snow load for low-slope roofs shall be obtained as follows.

Where p_g is equal to or less than the value of the minimum snow load upper limit, $p_{m,max}$, shown in Table 7.3-4:

$$p_m = p_g$$

Where p_g is greater than the value of the minimum snow load upper limit, $p_{m,max}$, shown in Table 7.3-4:

$$p_m = p_{m,max}$$

This minimum roof snow loads hall be a separate uniform load case. It need not be used in determining, or in combination with, drift, sliding, unbalanced, or partial loads.

7.4 SLOPED ROOF SNOW LOADS, p_s

Snow loads acting on a sloping surface shall be assumed to act on the horizontal projection of that surface. The sloped roof (balanced) snow load, p_s, shall be obtained by multiplying the flat roof snow load, p_f, by the roof slope factor, C_s:

$$p_s = C_s p_f \tag{7.4-1}$$

Table 7.3-1. Exposure Factor, C_e.

Surface Roughness Category	Exposure of Roof[a]		
	Fully Exposed[b]	Partially Exposed	Sheltered
B (see Section 26.7)	0.9	1.0	1.2
C (see Section 26.7)	0.9	1.0	1.1
D (see Section 26.7)	0.8	0.9	1.0
Above the tree line in windswept mountainous areas	0.7	0.8	N/A
In Alaska, in areas where trees do not exist within a 2 mi (3 km) radius of the site	0.7	0.8	N/A

The terrain category and roof exposure condition chosen shall be representative of the anticipated conditions during the life of the structure. An exposure factor shall be determined for each roof of a structure.

[a] Partially Exposed: All roofs not Fully Exposed or Sheltered. Fully Exposed: Roofs exposed on all sides with no shelter[b] afforded by terrain, higher structures, or trees. Roofs that contain several large pieces of mechanical equipment, parapets that extend above the height of the balanced snow load (h_b), or other obstructions are not in this category. Sheltered: Roofs located tight in among conifers that qualify as obstructions.

[b] Obstructions within a distance of $10h_o$ provide "shelter," where h_o is the height of the obstruction above the roof level. If the only obstructions are a few deciduous trees that are leafless in winter, the "fully exposed" category shall be used. Note that these are heights above the roof. Heights used to establish the Exposure Category in Section 26.7 are heights above the ground.

Table 7.3-2. Thermal Factor, C_t.

Thermal condition[a]	C_t
All structures except as indicated as follows	See Table 7.3-3
Unheated structures, open-air structures, structures kept just above freezing [40 to 50 °F (4 to 10 °C)], and other structures with cold, ventilated roofs meeting the minimum requirements of the applicable energy code	1.2
Freezer building	1.3
Continuously heated greenhouses[b] with a roof having a thermal resistance (R-value) less than 2.0 h·ft^2·°F/Btu (0.4 m^2·K/W) or a thermal transmittance (U-factor) greater than 0.5 Btu/h·ft^2·°F (2.5 W/m^2·K)	0.85

[a] These conditions shall be representative of the anticipated conditions during winters for the life of the structure.

[b] Greenhouses with a constantly maintained interior temperature of 50°F (10°C) or more, at any point 3 ft (0.9 m) above the floor level during winters and having either a maintenance attendant on duty at all times or a temperature alarm system to provide warning in the event of a heating failure.

@seismicisolation

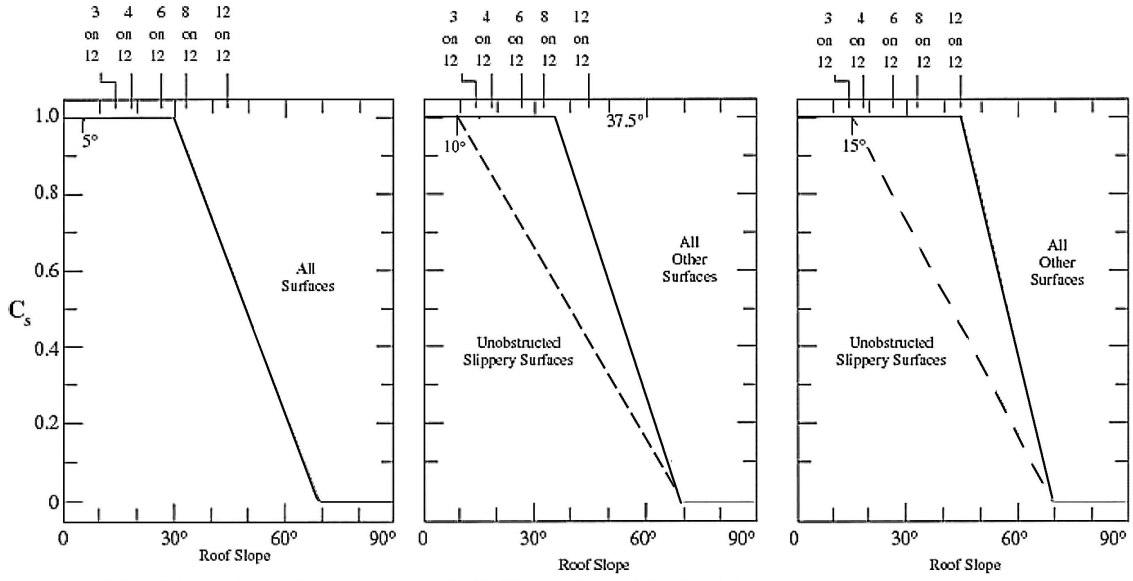
Table 7.3-3. Thermal Factor, C_t, for Heated Structures with Unventilated Roofs.[a]

R_{roof} (h·ft²·°F/Btu [m²·K/W])	U_{roof} (Btu/h·ft²·°F [W/m²·K])	P_g (psf [kPa]) ≤10 [0.48]	20 [0.96]	30 [1.44]	40 [1.92]	50 [2.40]	60 [2.88]	≥70 [3.36]
≤20 [3.52]	≥0.050 [0.284]	1.20	1.11	1.05	1.01	1.00	1.00	1.00
30 [5.28]	0.033 [0.189]	1.20	1.17	1.14	1.13	1.12	1.11	1.10
40 [7.04]	0.025 [0.142]	1.20	1.19	1.17	1.16	1.16	1.15	1.15
50 [8.80][b]	0.020 [0.114][b]	1.20	1.20	1.19	1.19	1.19	1.18	1.18

[a] For values of P_g and R_{roof} that fall between those shown in the table, linear interpolation may be used to determine the value of C_t.
[b] For values of $R_{roof} > 50$ h·ft²·°F/Btu (8.80 m²·K/W) or $U_{roof} < 0.020$ Btu/h·ft²·°F (0.114 W/m²·K), C_t should be taken as equal to 1.2.

Table 7.3-4. Minimum Snow Loads for Low-Slope Roofs.

Risk Category	$p_{m,max}$
I	25 lb/ft² (1.20 kN/m²)
II	30 lb/ft² (1.44 kN/m²)
III	35 lb/ft² (1.68 kN/m²)
IV	40 lb/ft² (1.92 kN/m²)



Values of C_s for warm roofs, cold roofs, curved roofs, and multiple roofs are determined from Sections 7.4.1 through 7.4.4. The thermal factor, C_t, from Table 7.3-2 determines if a roof is "cold" or "warm." "Slippery surface" values shall be used only where the roof's surface is unobstructed and sufficient space is available below the eaves to accept all the sliding snow. A roof shall be considered unobstructed if no objects exist on it that prevent snow on it from sliding. Roof areas with snow retention devices shall not be considered unobstructed. Slippery surfaces shall include metal, slate, glass, and bituminous, rubber, and plastic membranes with a smooth surface. Membranes with an embedded aggregate or mineral granule surface shall not be considered smooth. Asphalt shingles, wood shingles, and shakes shall not be considered slippery.

7.4.1 Slope Factor, C_s The slope factor, C_s, shall be determined using Figure 7.4-1, as outlined in Table 7.4-1.

7.4.2 Slope Factor for Curved Roofs Portions of curved roofs that have a slope exceeding 70 degrees shall be considered free of snow load (i.e., $C_s = 0$). Balanced loads shall be determined from the balanced load diagrams in Figure 7.4-2, with C_s determined from the appropriate curve in Figure 7.4-1.

7.4.3 Slope Factor for Multiple Folded Plate, Sawtooth, and Barrel Vault Roofs Multiple folded plate, sawtooth, or barrel vault roofs shall have a $C_s = 1.0$, with no reduction in snow load because of slope (i.e., $p_s = p_f$).

7.4.4 Ice Dams and Icicles along Eaves Unventilated roofs that drain water over their eaves shall be capable of sustaining a uniformly distributed load of $2p_f$ on all overhanging portions if the structure's thermal factor, C_t, is equal to or less than 1.1 per Section 7.3.2. The load on the overhang shall be based on the flat

7.4-1a: Warm roofs with $C_t = 1.1$ 7.4-1b: Warm roofs with $1.1 < C_t < 1.2$ 7.4-1c: Cold roofs with $C \geq 1.2$

Figure 7.4-1. Graphs for determining slope factor, C_s.
Note: See Tables 7.3-2 and 7.3-3 for C_t definitions.

@seismicisolation

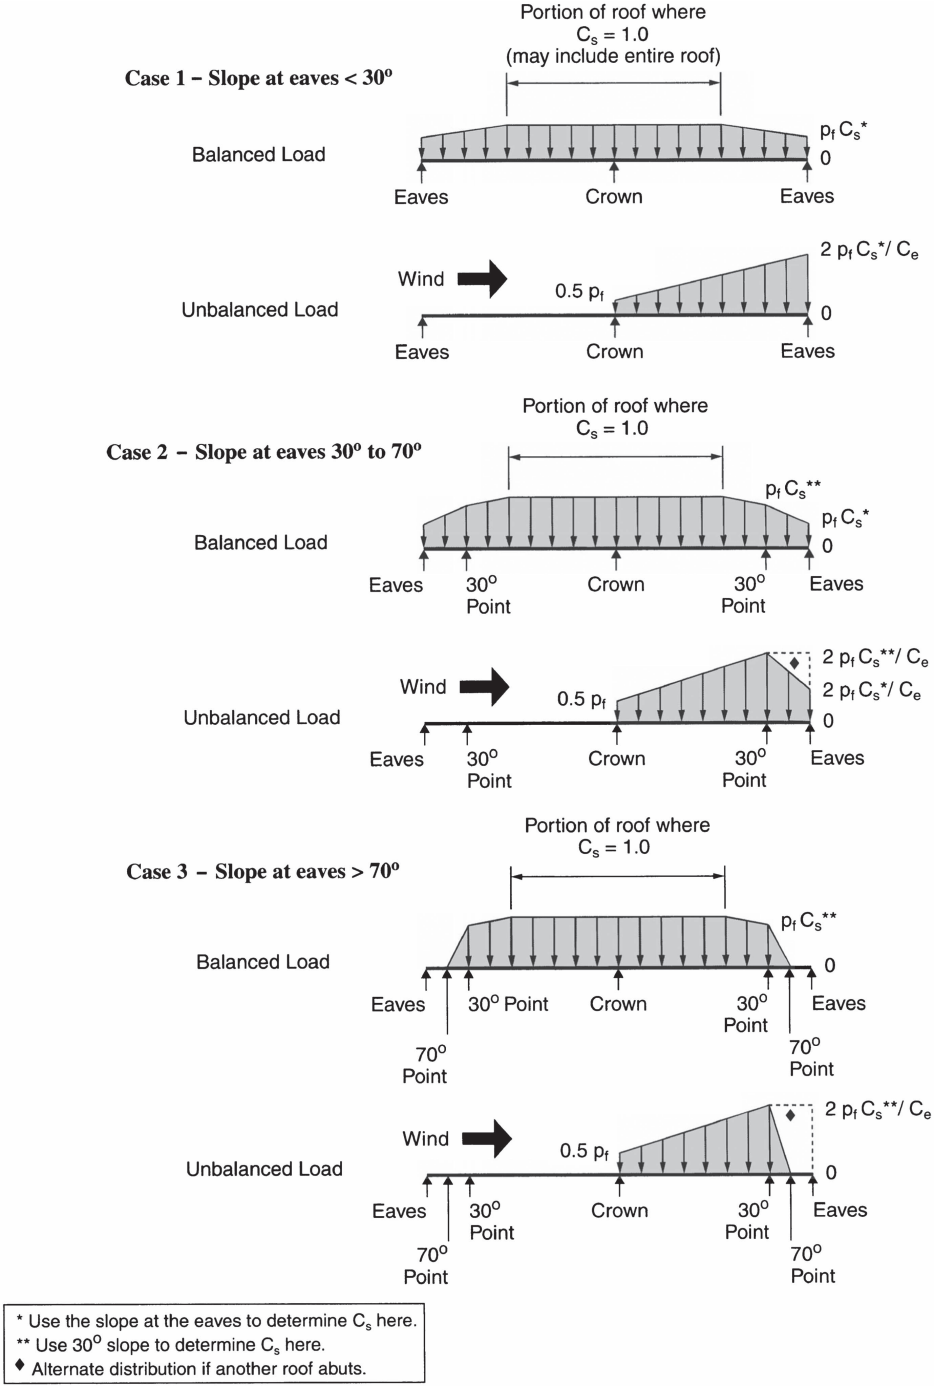


Figure 7.4-2. Balanced and unbalanced loads for curved roofs.

roof snow load for the heated portion of the roof upslope of the exterior wall. No other loads, except dead loads, shall be present on the roof when this uniformly distributed load is applied.

Where C_t is less than or equal to 1.1, the slope factor, C_s, shall be determined in accordance with Figure 7.4-1(a). Where C_t is greater than 1.1 and less than 1.2, the slope factor, C_s, shall be determined in accordance with Figure 7.4-1(b). Where C_t is equal to, or greater than, 1.2, the slope factor, C_s, shall be determined in accordance with Figure 7.4-1(c).

7.4.5 Sloped Roof Snow Loads for Air-Supported Structures Roof snow loading for air-supported structures with vinyl coated exterior fabric shall be as shown in Figure 7.4-3.

7.5 PARTIAL LOADING

The effect of having selected spans loaded with the balanced snow load, and remaining spans loaded with half the balanced snow load, shall be investigated as follows.

7.5.1 Continuous Beam Systems Continuous beam systems shall be investigated for the effects of the three loadings shown in Figure 7.5-1:

@seismicisolation

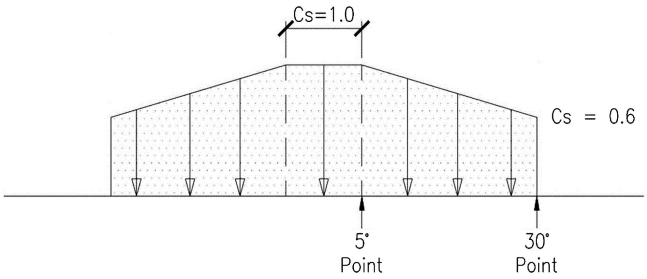

Figure 7.4-3. Sloped roof snow load for air-supported structures.

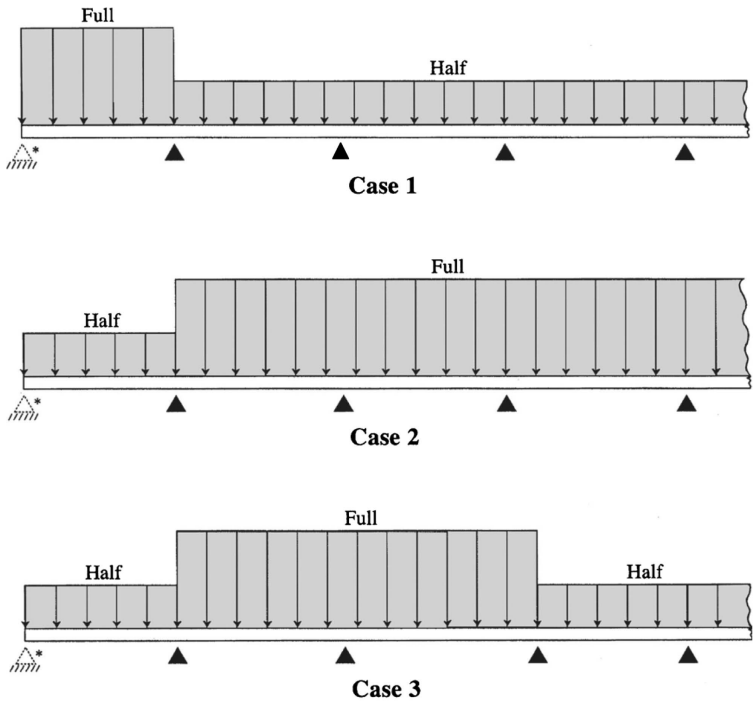
Case 1: Full balanced snow load on either exterior span and half the balanced snow load on all other spans.

Case 2: Half the balanced snow load on either exterior span and full balanced snow load on all other spans.

Case 3: All possible combinations of full balanced snow load on any two adjacent spans and half the balanced snow load on all other spans. For this case, there will be (n–1) possible combinations, where n equals the number of spans in the continuous beam system.

If a cantilever is present in any of the above cases, it shall be considered to be a span.



Partial load provisions need not be applied to structural members that span perpendicular to the ridgeline in gable roofs with slopes between 1/2 on 12 (2.38 degrees) and 7 on 12 (30.3 degrees).

7.5.2 Other Structural Systems Areas sustaining only half the balanced snow load shall be chosen so as to produce the greatest effects on members being analyzed.

7.6 UNBALANCED ROOF SNOW LOADS

Balanced and unbalanced loads shall be analyzed separately. Winds from all directions shall be accounted for when establishing unbalanced loads.

7.6.1 Unbalanced Snow Loads for Hip and Gable Roofs For hip and gable roofs with a slope exceeding 7 on 12 (30.2 degrees), or with a slope less than 1/2 on 12 (2.38 degrees), unbalanced snow loads are not required to be applied. Roofs with an eave to ridge distance, W, of 20 ft (6.1 m) or less that have simply supported prismatic members spanning from ridge to eave shall be designed to resist an unbalanced uniform snow load on the leeward side equal to p_g. For these roofs, the windward side shall be unloaded. For all other gable roofs, the unbalanced load shall consist of $0.3p_s$ on the windward side, p_s on the leeward side plus a rectangular surcharge with magnitude $h_d\gamma/\sqrt{S}$ and horizontal extent from the ridge $8h_d\sqrt{S}/3$ where h_d is the drift height from Equation (7.6-1) with l_u equal to the eave to ridge distance for the windward portion of the roof, W.

* The left supports are dashed since they would not exist when a cantilever is present.

Figure 7.5-1. Partial loading diagrams for continuous beams.

@seismicisolation

The drift height h_d is given by

$$h_d = 1.5\sqrt{\frac{P_g^{0.74} l_u^{0.70} W_2^{1.7}}{\gamma}} \qquad (7.6\text{-}1)$$

where the winter wind parameter W_2 for the site is given in Figure 7.6-1 and Table 7.2-1 for Alaska.

Balanced and unbalanced loading diagrams are presented in Figure 7.6-2.

User Note: The winter wind parameter W_2 is available at https://asce7hazardtool.on-line/.

7.6.2 Unbalanced Snow Loads for Curved Roofs Portions of curved roofs that have a slope exceeding 70 degrees shall be considered free of snow load. If the slope of a straight line from the eaves (or the 70-degree point, if present) to the crown is less than 10 degrees or greater than 60 degrees, unbalanced snow loads shall not be taken into account.

Unbalanced loads shall be determined according to the loading diagrams in Figure 7.4-2. In all cases, the windward side shall be considered free of snow. If the ground or another roof abuts a Case 2 or Case 3 (see Figure 7.4-2) curved roof at or within 3 ft (0.9 m) of its eaves, the snow load shall not be decreased between the 30 degree point and the eaves but shall remain constant at the 30-degree point value. This distribution is shown as a dashed line in Figure 7.4-2.

7.6.3 Unbalanced Snow Loads for Multiple Folded Plate, Sawtooth, and Barrel Vault Roofs Unbalanced loads shall be applied to folded plate, sawtooth, and barrel-vaulted multiple roofs with a slope exceeding 3/8 in. on 12 (1.79 degrees). According to Section 7.4.4, $C_s = 1.0$ for such roofs, and the balanced snow load equals p_f. The unbalanced snow load shall increase from one-half the balanced load at the ridge or crown (i.e., $0.5p_f$) to two times the balanced load given in Section 7.4.4 divided by C_e at the valley (i.e., $2p_f/C_e$). Balanced and unbalanced loading diagrams for a sawtooth roof are presented in Figure 7.6-3. However, the snow surface above the valley shall not be at an elevation higher than the snow above the ridge. Snow depths shall be determined by dividing the snow load by the density of that snow from Equation (7.7-1).

7.6.4 Unbalanced Snow Loads for Dome Roofs Unbalanced snow loads shall be applied to domes and similar rounded structures. Snow loads, determined in the same manner as for curved roofs in Section 7.6.2, shall be applied to the downwind 90 degree sector in plan view. At both edges of this sector, the load shall decrease linearly to zero over sectors of 22.5 degrees each. There shall be no snow load on the remaining 225 degree upwind sector.

7.7 DRIFTS ON LOWER ROOFS (AERODYNAMIC SHADE)

Roofs shall be designed to sustain localized loads from snow-drifts that form in the wind shadow of (1) higher portions of the same structure, and (2) adjacent structures and terrain features.

7.7.1 Lower Roof of a Structure Snow that forms drifts comes from a higher roof or, with the wind from the opposite direction, from the roof on which the drift is located. These two kinds of drifts ("leeward" and "windward," respectively) are shown in Figure 7.7-1. The geometry of the surcharge load due to snow drifting shall be approximated by a triangle, as shown in Figure 7.7-2. Drift loads shall be superimposed on the balanced snow load. If h_c/h_b is less than 0.2, drift loads are not required to be applied.

For leeward drifts, the drift height, h_d, shall be determined directly from Equation (7.6-1) using the length of the upper roof. However, the drift height need not be taken as larger than 60% of the length of the lower level roof. For windward drifts, the drift height shall be determined by substituting the length of the lower roof for l_u into Equation (7.6-1) and using three-quarters of h_d as the drift height. The larger of these two heights shall be used in design. For leeward drifts, if h_d is equal to or less than h_c, the drift width, w, shall equal $4h_d$ and the drift height shall equal h_d. If this height exceeds h_c, the drift width, w, shall equal $4h_d^2/h_c$ and the drift height shall equal h_c.

For leeward drifts, the drift width, w, shall not be greater than $8h_c$. For windward drifts, the drift width shall be taken as eight times the windward drift height or $(8(.75h_d) = 6h_d)$. If the drift width for either windward or leeward drifts, w, exceeds the width of the lower roof, the drift shall taper linearly to zero at the far end of the lower level roof. Windward and leeward drifts shall be checked independently to determine which controls the structural design of each member. The maximum intensity of the drift surcharge load, p_d, equals $h_d\gamma$, where snow density, γ, is defined in Equation (7.7-1):

$$\gamma = 0.13p_g + 14 \text{ but not more than } 30 \text{ lb/ft}^3 \qquad (7.7\text{-}1)$$

$$\gamma = 0.426p_g + 2.2, \text{ but not more than } 4.7 \text{ kN/m}^3 \qquad (7.7\text{-}1.\text{SI})$$

This density shall also be used to determine h_b by dividing p_s by γ (in SI: also multiply by 102 to get the depth in m).

7.7.2 Adjacent Structures If the horizontal separation distance between adjacent structures, s, is less than 20 ft (6.1 m) and less than six times the vertical separation distance ($s < 6h$), then the requirements for the leeward drift of Section 7.7.1 shall be used to determine the drift load on the lower structure. The height of the snow drift shall be the smaller of h_d, based on the length of the adjacent higher structure, and $(6h-s)/6$. The horizontal extent of the drift shall be the smaller of $6h_d$ or $(6h-s)$.

For windward drifts, the requirements of Section 7.7.1 shall be used. The resulting drift is permitted to be truncated.

7.7.3 Intersecting Drifts Intersecting drifts shall be evaluated at reentrant corners, parapet wall corners, intersections of gable roof with the roof step wall of a taller roof and other similar geometries. Section 7.7.1 shall be used to determine the snow drift geometry for each direction. Where the two snowdrifts intersect, the larger of the two snowdrift depths shall govern, as shown in Figure 7.7-3. Intersecting snowdrift loads shall be considered to occur concurrently, except that the two drift loads need not be superimposed.

For leeward intersecting snowdrifts at reentrant corners, the length of the upper roof applicable for each snowdrift shall be used with l_u parallel to w_1 for the first drift and l_u parallel to w_2 for the second drift. For windward snowdrifts, the lengths of the lower roof shall be used for l_u.

7.8 ROOF PROJECTIONS AND PARAPETS

The method for windward drifts in Section 7.7.1 shall be used to calculate drift loads on all sides of roof projections and at parapet walls. The height of such drifts shall be taken as three-quarters the drift height from Equation 7.6-1 (i.e., $0.75h_d$). For parapet walls, l_u shall be taken equal to the length of the roof upwind of the wall. For roof projections, l_u shall be taken equal to the greater of the length of the roof upwind or downwind of the projection.

@seismicisolation

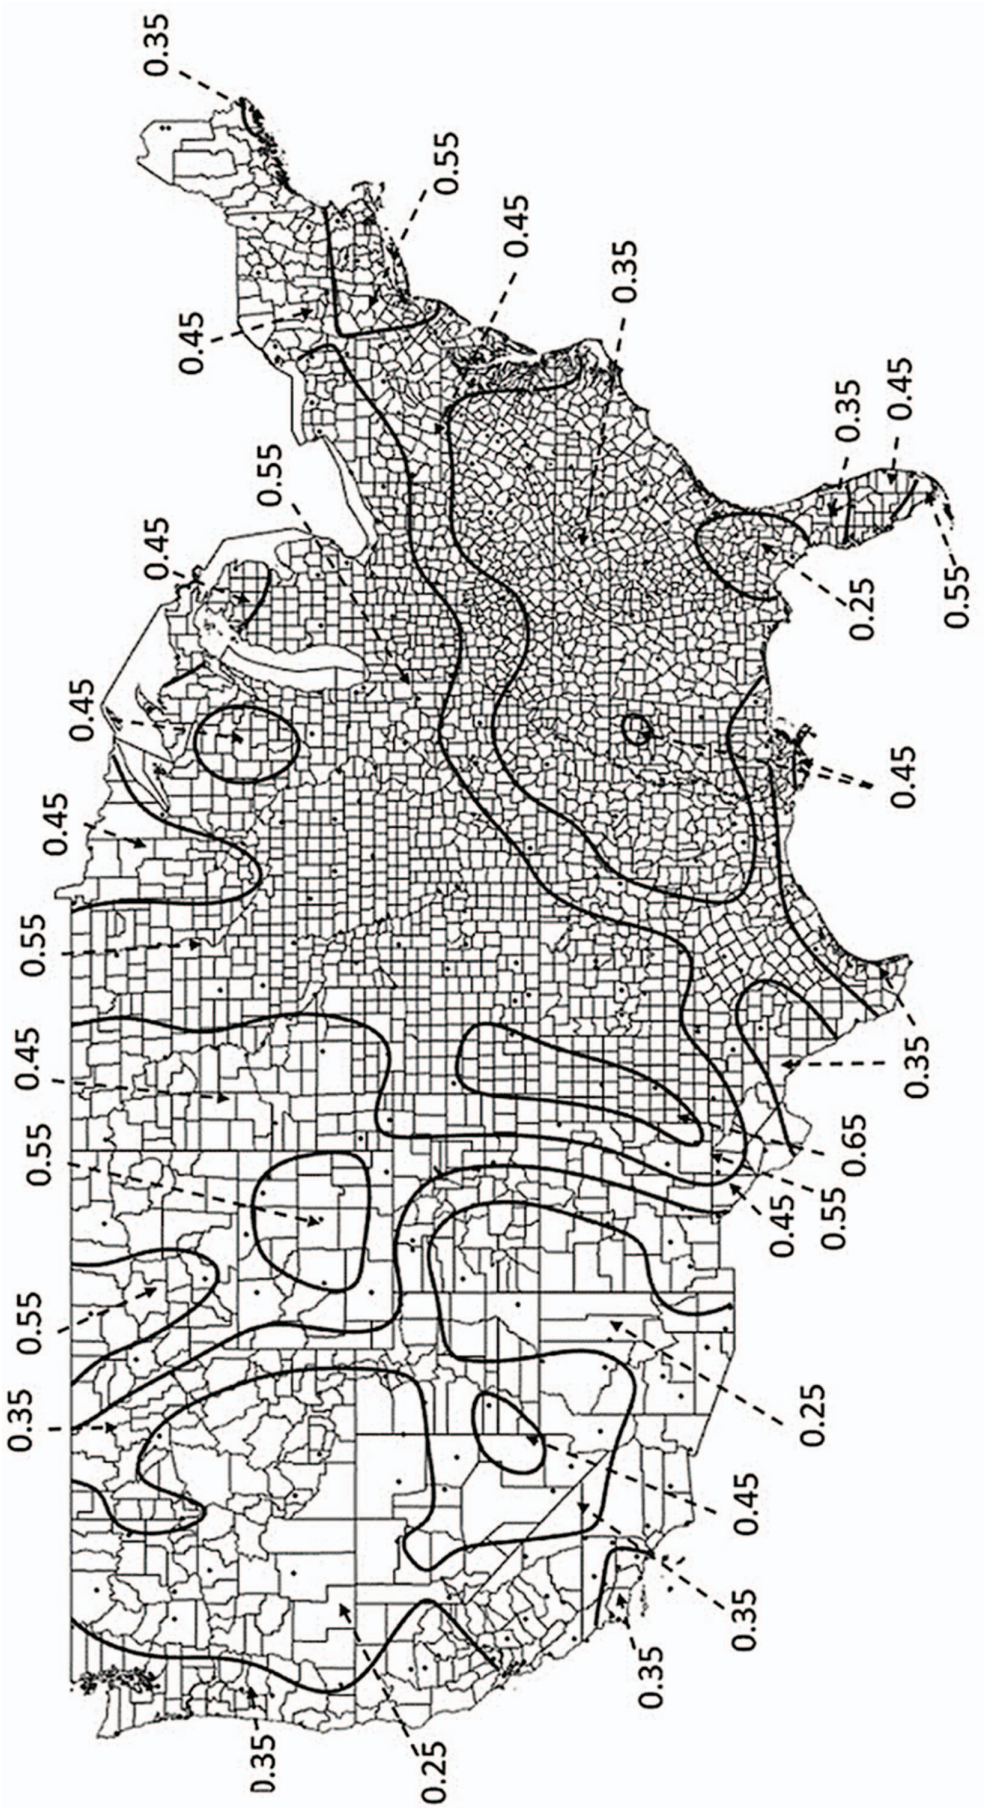


Figure 7.6-1. Map of winter wind parameter, W_2.

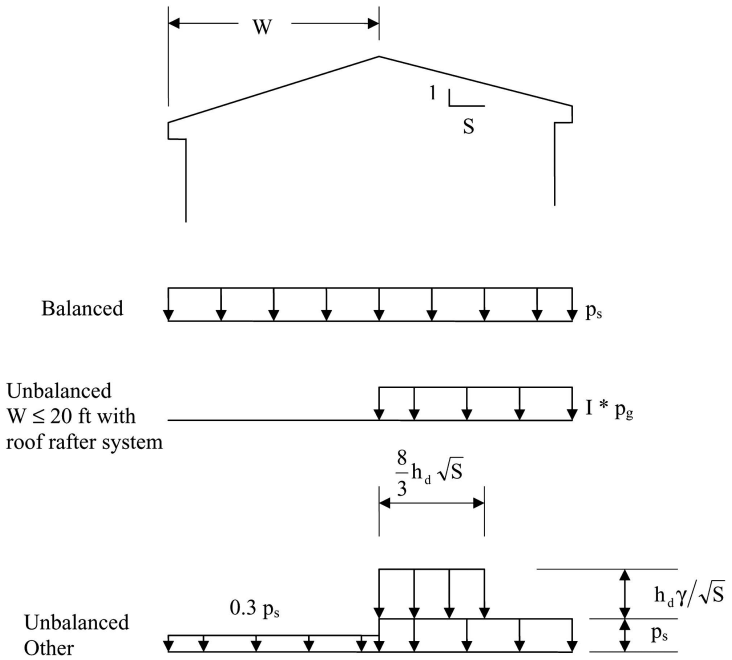
Note: The winter wind parameter W_2 is available at https://asce7hazardtool.on-line.

@seismicisolation



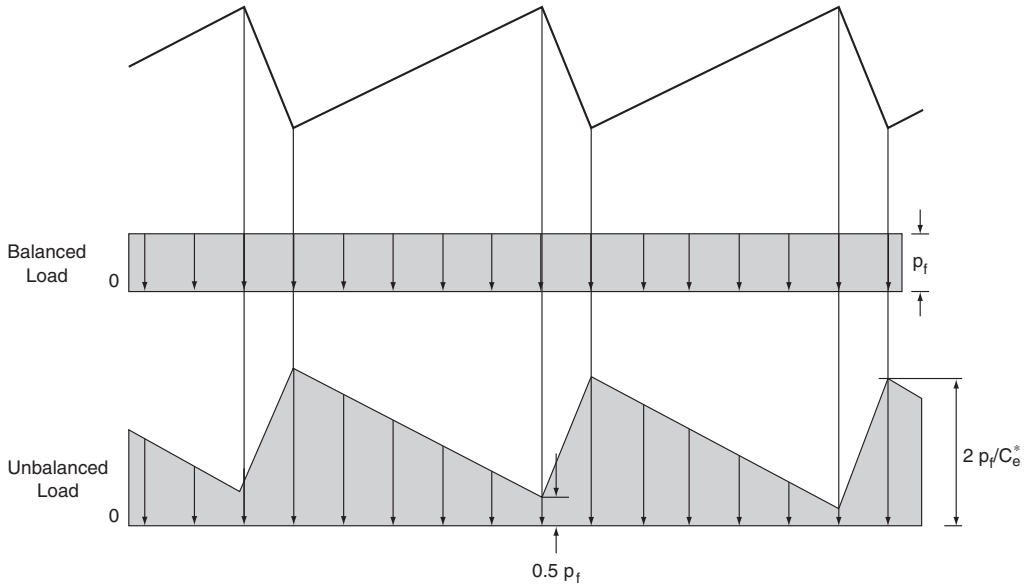


Figure 7.6-2. Balanced and unbalanced snow loads for hip and gable roofs.

Note: Unbalanced loads need not be considered for $\theta > 30.2°$ (7 on 12) or for $\theta < 2.38°$ (1/2 on 12).

* May be somewhat less; see Section 7.6.3

Figure 7.6-3. Balanced and unbalanced snow loads for a sawtooth roof.

EXCEPTION: Drift loads shall not be required where the side of the roof projection is less than 15 ft (4.6 m) or the clear distance between the height of the balanced snow load, h_b, and the bottom of the projection (including horizontal supports) is at least 2 ft (0.61 m).

7.9 SLIDING SNOW

The load caused by snow sliding off a sloped roof onto a lower roof shall be determined for slippery upper roofs with slopes greater than ¼ on 12, and for other (i.e., nonslippery) upper roofs with slopes greater than 2 on 12. The total sliding load per unit length of eave shall be $0.4 p_f W$, where W is the horizontal distance from the eave to ridge for the sloped upper roof. The sliding load shall be distributed uniformly on the lower roof over a distance of 15 ft (4.6 m) from the upper roof eave. If the width of the lower roof is less than 15 ft (4.6 m), the sliding load shall be reduced proportionally.

The sliding snow load shall not be further reduced unless a portion of the snow on the upper roof is blocked from sliding onto the lower roof by snow already on the lower roof.

For separated structures, sliding loads shall be considered when $h/s > 1$ and $s < 15$ ft ($s < 4.6$ m). The horizontal extent of the sliding load on the lower roof shall be $15–s$ with s in feet

@seismicisolation

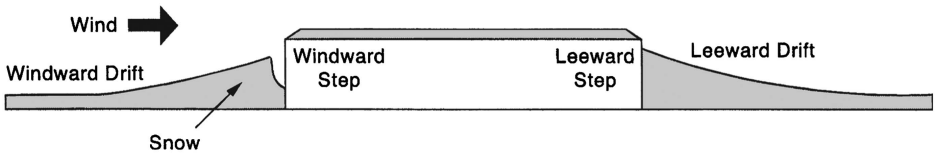

Figure 7.7-1. Drifts formed at windward and leeward steps.

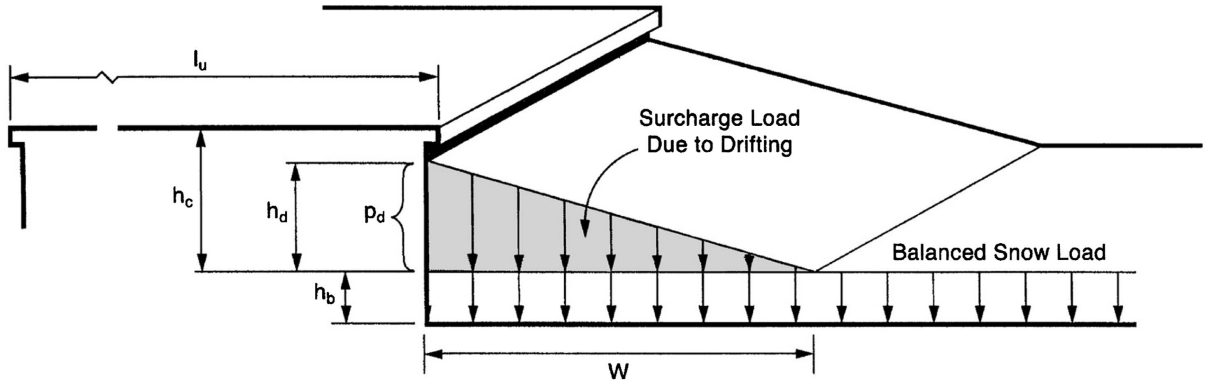

Figure 7.7-2. Configuration of snowdrifts on lower roofs.

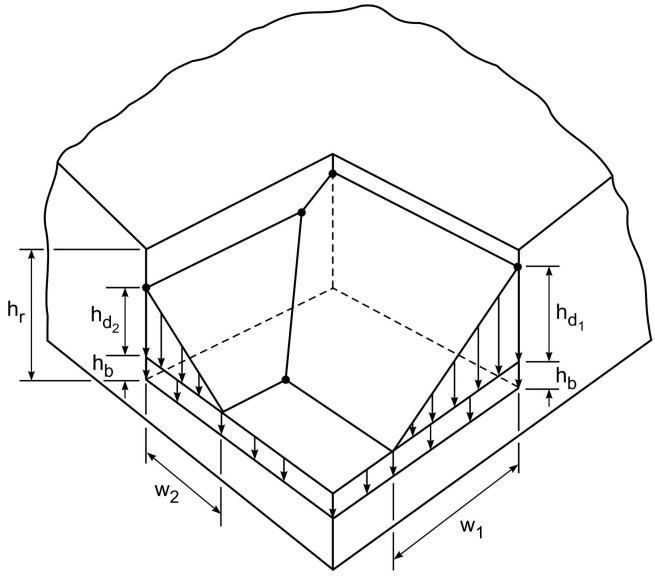

Figure 7.7-3. Configuration of intersecting snowdrifts at lower roof.

(4.6−s with s in meters), and the load per unit length shall be $0.4p_f W(15-s)/15$ with s in feet ($0.4p_f W(4.6-s)/4.6$ with s in meters).

Sliding loads shall be superimposed on the balanced snow load and need not be used in combination with drift, unbalanced, partial, or rain-on-snow loads.

7.10 RAIN-ON-SNOW SURCHARGE LOAD

For locations where p_g is less than, or equal to, the value of $p_{m,max}$ given in Table 7.3-4, but not zero, all roofs with slopes (in degrees) less than $W/50$ with W in ft (in SI: $W/15.2$ with W in m) shall include a 8 lb/ft^2 (0.38 kN/m^2) rain-on-snow surcharge load. This additional load applies only to the sloped roof (balanced) load case and need not be used in combination with drift, sliding, unbalanced, minimum, or partial loads.

7.11 PONDING INSTABILITY

Susceptible bays shall be designed to preclude ponding instability. Roof deflections caused by full snow loads shall be evaluated when determining the likelihood of ponding instability.

7.12 EXISTING ROOFS

Existing roofs shall be evaluated for increased snow loads caused by additions or alterations. Owners or agents for owners of an existing lower roof shall be advised of the potential for increased snow loads, where a higher roof is constructed within 20 ft (6.1 m). See footnote to Table 7.3-1 and Section 7.7.2.

7.13 SNOW ON OPEN-FRAME EQUIPMENT STRUCTURES

Open-frame equipment structures shall be designed for snow loads in accordance with Sections 7.13.1 through 7.13.4. The thermal factor, $C_t = 1.2$, shall be used in determination of snow loads for unheated open-frame equipment structures.

7.13.1 Snow at Top Level Flat roof snow loads (p_f) and drift loads shall be applied at the top level of the structure where there is flooring or elements that can retain snow. Open-frame members with a width of more than 8 in. (200 mm) shall be considered snow retaining surfaces. The top level shall be designed for snowdrifts, in accordance with Sections 7.7 and 7.9, where there are wind walls or equivalent obstructions.

7.13.2 Snow at Levels below the Top Level At all levels with flooring (grating, checkered plate, etc.) located below a level with

@seismicisolation

flooring, the flat roof snow load shall be applied over a portion of that flooring level near any open edge in accordance with Figure 7.13-1. The flat roof snow load shall extend from the upwind edge of the flooring a horizontal distance equal to the vertical difference in elevation between the level in question and the next floor above.

7.13.3 Snow Loads on Pipes and Cable Trays Individual pipes and cable trays with a diameter (pipe) or width (tray) less than or equal to $0.73p_f/\gamma$ shall be designed for a triangular snow load in accordance with Figure 7.13-2(a). Individual pipes and cable trays with a diameter (pipe) or width (tray) greater than $0.73p_f/\gamma$ shall be designed for a trapezoidal snow load, in accordance with Figure 7.13-2(b). Snow loads on pipes are not required to be considered if the wintertime external surface temperature of the pipe is greater than 45 °F (7.2 °C).

Where the spacing between multiple adjacent pipes or cable trays at the same elevations is less than the height of the flat roof snow load (p_f/γ), an additional uniform cornice load of p_f shall be applied in the spaces between the pipes or cable trays, as shown in Figure 7.13-3. For $S_p \geq h$, the additional cornice loads need not be applied.

7.13.4 Snow Loads on Equipment and Equipment Platforms Snow loads on the structure shall include snow accumulation on equipment and equipment platforms that can retain snow. Snow accumulation need not be considered on equipment with a wintertime external surface temperature greater than 45°F (7.2°C).

7.14 ALTERNATE PROCEDURE

In lieu of the requirements specified in Sections 7.3 through 7.13, the design snow loads shall be permitted to be determined by thermal performance studies and scale-model studies in wind tunnels or water flumes conducted in accordance with the requirements of ASCE 49 and this section. Snow loads determined using these studies shall be based on the ground snow loads outlined in Section 7.2 and shall be derived to be consistent with the reliability targets outlined in Chapter 1.

7.14.1 Limitations on Snow Loads Derived from Scale Model Studies Snow loads derived based on scale-model studies shall not be taken as less than 80% of those specified in Sections 7.2 through 7.13 unless an independent peer review

Note: D, pipe diameter $+2x$ insulation thickness (as applicable); P_f, flat roof snow load; θ, assumed angle of repose = 70 degrees.

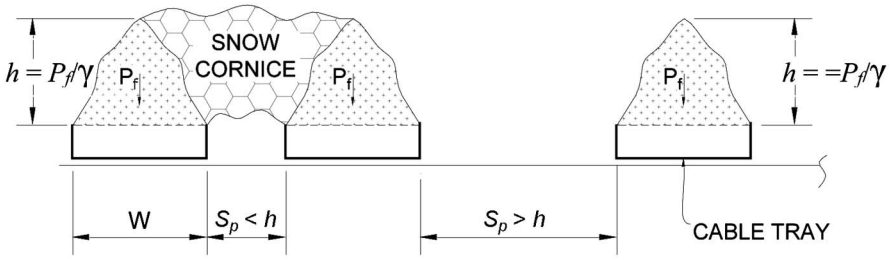

Figure 7.13-3. Snow load on multiple cable trays/pipes at same elevation.

is conducted in accordance with Section 1.3.1.3.4. When an independent peer review is conducted, the design snow loads shall not be taken as less than 60% of those specified in Sections 7.2 through 7.13.

7.14.2 Consideration of Thermal Performance in Model Studies If the study includes an assessment of the thermal performance of the building or structure, the roof insulation value shall not be taken as less than R20 [U=0.05 Btu/(h ft^2 °F)] and the internal temperature shall not be taken as greater than 70 °F, with the exception of continuously heated greenhouses as outlined in Table 7.3-2, where the expected thermal properties and internal temperatures may be considered. In lieu of modeling the thermal performance, the thermal factor outlined in Section 7.3.2 is permitted to be applied to the scale model snow load.

7.15 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

This section lists the consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

CHAPTER 8
RAIN LOADS

8.1 DEFINITIONS AND SYMBOLS

8.1.1 Definitions

BAY: A portion of the roof bounded by adjacent column lines or structural walls.

CONTROLLED FLOW ROOF DRAIN: A roof drain designed to intentionally regulate the rate of drainage.

PONDING: The accumulation of water caused by the deflection of the roof structure, resulting in added load.

PONDING INSTABILITY: Member instability caused by progressive deflection because of ponding on roofs.

PRIMARY DRAINAGE SYSTEM: Roof drainage system through which water is normally conveyed off the roof.

SECONDARY DRAINAGE SYSTEM FOR STRUCTURAL LOADING (SDSL): Roof drainage system through which water is drained from the roof when the drainage systems listed in Section 8.2 (a) through (d) are blocked or not working.

SECONDARY MEMBER: For the purposes of Section 8.3, structural members not having direct attachment to the columns.

8.1.2 Symbols

d_h = Hydraulic head equal to the depth of water on the undeflected roof above the inlet of the secondary drainage system for structural loading (SDSL) required to achieve the design flow, in. (mm)

d_s = Static head equal to the depth of water on the undeflected roof up to the inlet of the secondary drainage system for structural loading (SDSL), in. (mm)

d_p = Ponding head equal to the depth of water due to deflections of the roof subjected to unfactored rain load and unfactored dead load in. (mm)

L_s = Span of secondary members, in. (mm)

S = Spacing of secondary members, in. (mm)

R = Rain load, lb/ft^2 (kN/m^2)

8.2 DESIGN RAIN LOADS

Each portion of a roof shall be designed to sustain the load of all rainwater that will accumulate on it, assuming all drainage systems that meet any of the following criteria are blocked:

(a) The primary drainage system,
(b) Secondary drainage systems with an inlet that is vertically separated from the inlet to the primary drainage system by less than 2 in. (51 mm),
(c) Secondary drainage systems that share drain lines with the primary drainage system, or
(d) Secondary drainage systems with controlled flow roof drains.

Rain loads shall be based on the summation of the static head, d_s, hydraulic head, d_h, and ponding head, d_p, using Equation (8.2-1). The hydraulic head shall be based on hydraulic test data or hydraulic calculations, assuming a flow rate corresponding to a rainfall intensity equal to or greater than the 15 min duration storm with return period (frequency) given in Table 8.2-1. The ponding head shall be based on structural analysis as the depth of water caused by deflections of the roof subjected to unfactored rain load and unfactored dead load.

$$R = 5.2(d_s + d_h + d_p) \tag{8.2-1}$$

$$R = 0.0098(d_s + d_h + d_p) \tag{8.2-1.SI}$$

8.3 BAYS WITH LOW SLOPE

Free-draining bays and internal bays not subjected to accumulated rain load required by Section 8.2 shall have adequate strength and stiffness to preclude progressive deflection (i.e., instability) and resist potential ponding rain loads where either of the following conditions are met:

1. The roof slope is less than 1/4 in. per foot (1.19 degrees), or
2. The bay is adjacent to a free-draining edge with secondary members parallel to the free-draining edge and the roof slope is less than β where $\beta = (L_s/S + \pi)/20$ (in. per foot).

8.4 DRAINAGE TO EXISTING ROOFS

Drainage systems for new construction shall not discharge water onto existing roofs unless the existing roof is evaluated and either is able to support the loads determined using this chapter or is upgraded to support the loads determined using this chapter.

8.5 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

No consensus standards and other documents that shall be considered part of this standard are referenced in this chapter.

Table 8.2-1. Design Storm Return Period by Risk Category.

Risk Category	Design Storm Return Period
I and II	100 years
III	200 years
IV	500 years

CHAPTER 10
ICE LOADS—ATMOSPHERIC ICING

10.1 GENERAL

Atmospheric ice loads caused by freezing rain, snow, and in-cloud icing shall be considered in the design of ice-sensitive structures. In areas where records or experience indicate that snow or in-cloud icing produces larger loads than freezing rain, site-specific studies shall be used. Structural loads caused by hoarfrost are not a design consideration. Roof snow loads are covered in Chapter 7.

10.1.1 Site-Specific Studies Site-specific studies that are acceptable to the Authority Having Jurisdiction shall be used to determine the ice thickness or load for the applicable Risk Category, concurrent wind speed, and concurrent temperature in

1. Areas where records or experience indicate that snow or in-cloud icing produce larger loads than freezing rain;
2. Special icing regions, as shown in Figures 10.4-2 through 10.4-5; and
3. Complex terrain, where examination indicates unusual icing conditions exist.

10.1.2 Dynamic Loads Dynamic loads, such as those resulting from galloping, ice shedding, and aeolian vibrations, which are caused, or enhanced, by an ice accretion on a flexible structural member, component, or appurtenance, are not covered in this section.

10.1.3 Exclusions Electrical supply and communication systems, communications towers and masts, and other structures for which national standards exist are excluded from the requirements of this section. Applicable standards and documents include the National Electrical Safety Code, ASCE Manual of Practice 74, and ANSI/TIA-222.

10.2 DEFINITIONS

The following definitions apply only to the provisions of this chapter.

ATMOSPHERIC ICE GEODATABASE: The ASCE database (version 2022-1.0) of geocoded nominal ice thickness, concurrent wind, and concurrent temperature data.

COMPONENTS AND APPURTENANCES: Nonstructural elements that may be exposed to atmospheric icing. Examples include ladders, handrails, netting, antennas, waveguides, radio frequency (RF) transmission lines, pipes, electrical conduits, and cable trays.

FREEZING RAIN: Rain or drizzle that falls into a layer of subfreezing air at the Earth's surface and freezes on the ground or an object to form glaze ice.

GLAZE: Clear, high-density ice.

HOARFROST: An accumulation of ice crystals formed by the direct deposition of water vapor from the air onto an object.

ICE-SENSITIVE STRUCTURES: Structures for which the effect of an atmospheric icing load governs the design of part, or all, of the structure. These structures include, but are not limited to, lattice structures, guyed masts, overhead electric and communication lines, light suspension and cable-stayed bridges, aerial cable systems (e.g., for ski lifts and logging operations), amusement rides, open catwalks and platforms, flagpoles, and signs.

IN-CLOUD ICING: Icing that occurs when supercooled cloud or fog droplets, carried by the wind, freeze on objects. In-cloud icing usually forms rime but may also form glaze.

RIME: White or opaque ice with entrapped air.

SNOW: Snow that adheres to objects by some combination of capillary forces, freezing, and sintering.

10.3 SYMBOLS

A_i = Cross-sectional area of ice, ft^2 (m^2)
A_s = Surface area of one side of a flat plate or the projected area of complex shapes, ft^2 (m^2)
D = Diameter of a circular structure or member, as defined in Chapter 29, ft (m)
D_c = Diameter of the cylinder circumscribing an object, ft (m)
f_z = Factor to account for the increase in ice thickness with height
K_{zt} = Topographic factor, as defined in Chapter 26
q_z = Velocity pressure evaluated at height, z, as defined in Chapter 29, lb/ft^2 (N/m^2)
r = Radius of the maximum cross section of a dome or radius of a sphere, ft (m)
t = Nominal ice thickness on a cylinder caused by freezing rain at a height of 33 ft (10 m), from Figures 10.4-2 through 10.4-5, for the applicable risk category, in. (mm)
t_d = Design ice thickness from Equation (10.4-5), in. (mm)
V_c = Concurrent gust speed, from Figures 10.5-1 and 10.5-2, mph (m/s)
V_i = Volume of ice, ft^3 (m^3)
z = Height above ground, ft (m)
ε = Solidity ratio, as defined in Chapter 29

10.4 ICE LOADS CAUSED BY FREEZING RAIN

10.4.1 Ice Load The ice load shall be determined using the volume or cross-sectional area of glaze ice formed on all exposed surfaces of structural members, guys, components, appurtenances, and cable systems. On structural shapes, prismatic members, and other similar shapes, the cross-sectional area of ice shall be determined by

@seismicisolation
@seismicisolation

$$A_i = \pi \frac{t_d}{12}\left(D_c + \frac{t_d}{12}\right) \quad (10.4\text{-}1)$$

$$A_i = \pi \frac{t_d}{1000}\left(D_c + \frac{t_d}{1000}\right) \quad (10.4\text{-}1\text{SI})$$

D_c is shown for a variety of cross-sectional shapes in Figure 10.4-1.

On flat plates and large three-dimensional objects such as domes and spheres, the volume of ice shall be determined by

$$V_i = \pi \frac{t_d}{12} A_s \quad (10.4\text{-}2)$$

$$V_i = \pi \frac{t_d}{1000} A_s \quad (10.4\text{-}2\text{SI})$$

For a flat plate, A_s shall be the area of one side of the plate; for domes and spheres, A_s shall be determined by

$$A_s = \pi r^2 \quad (10.4\text{-}3)$$

It is acceptable to multiply V_i by 0.8 for vertical plates and 0.6 for horizontal plates.

The ice density shall be not less than 56 pcf (900 kg/m^3).

10.4.2 Nominal Ice Thickness The nominal ice thickness is the equivalent radial glaze ice thickness. Figures 10.4-2 through 10.4-5 show the nominal ice thicknesses, t, from freezing rain, at a height of 33 ft (10 m), over the contiguous 48 states and Alaska for Risk Categories I, II, III, and IV. Ice thicknesses for Hawaii shall be obtained from local meteorological studies.

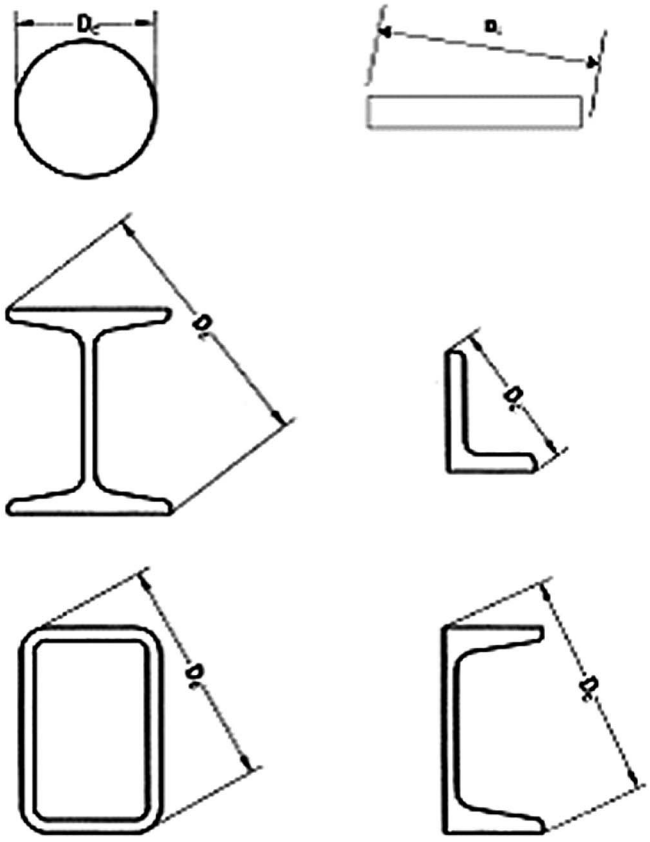

Figure 10.4-1. Characteristic dimension, D_c, for calculating the ice area for a variety of cross-sectional shapes.

10.4.3 Height Factor The height factor, f_z, used to increase the radial thickness of ice for height above ground, z, shall be determined by

$$f_z = \left(\frac{z}{33}\right)^{0.10} \quad \text{for } 0\,\text{ft} < z \le 900\,\text{ft} \quad (10.4\text{-}4)$$

where $f_z = 1.4$ for $z > 900$ ft.

$$f_z = \left(\frac{z}{10}\right)^{0.10} \quad \text{for } 0\,\text{m} < z \le 275\,\text{m} \quad (10.4\text{-}4\text{.SI})$$

where $f_z = 1.4$ for $z > 275$ m.

10.4.4 Topographic Factor Both the ice thickness and concurrent gust speed for structures on hills, ridges, and escarpments are higher than those on level terrain because of wind speed-up effects. The topographic factor for the concurrent wind pressure is K_{zt}, and the topographic factor for ice thickness is $(K_{zt})^{0.35}$, where K_{zt} is obtained from Equation (26.8-1).

10.4.5 Design Ice Thickness for Freezing Rain The design ice thickness t_d shall be calculated from Equation (10.4-5).

$$t_d = t f_z (K_{zt})^{0.35} \quad (10.4\text{-}5)$$

10.5 WIND ON ICE-COVERED STRUCTURES

Ice accreted on structural members, components, and appurtenances increases the projected area of the structure exposed to wind. The projected area shall be increased by adding t_d to all free edges of the projected area. Wind loads on this increased projected area shall be used in the design of ice-sensitive structures. Figures 10.5-1 and 10.5-2 show 3s gust speeds at 33 ft (10 m) above grade that are concurrent with the ice loads caused by freezing rain. These gust speeds shall be used with nominal ice thicknesses for all risk categories. Wind loads shall be calculated in accordance with Chapters 26 through 31, as modified by Sections 10.5.1 through 10.5.5.

10.5.1 Wind on Ice-Covered Chimneys, Tanks, and Similar Structures Force coefficients, C_f, for structures with square, hexagonal, and octagonal cross sections shall be as given in Figure 29.4-1. Force coefficients, C_f, for structures with round cross sections shall be as given in Figure 29.4-1 for the entry round, $D\sqrt{q_z} \le 2.5$ for all ice thicknesses, wind speeds, and structure diameters.

10.5.2 Wind on Ice-Covered Solid Freestanding Walls and Solid Signs Force coefficients, C_f, shall be as given in Figure 29.3-1, based on the dimensions of the wall or sign, including ice.

10.5.3 Wind on Ice-Covered Open Signs and Lattice Frameworks The solidity ratio, ε, shall be based on the projected area, including ice. The force coefficient, C_f, for the projected area of flat members shall be as given in Figure 29.4-2. The force coefficient, C_f, for rounded members and for the additional projected area caused by ice on both flat and rounded members shall be as given in Figure 29.4-2 for rounded members with $D\sqrt{q_z} \le 2.5$ for all ice thicknesses, wind speeds, and member diameters.

@seismicisolation

10.5.4 Wind on Ice-Covered Trussed Towers The solidity ratio, ε, shall be based on the projected area, including ice. The force coefficients, C_f, shall be as given in Figure 29.4-3. It is acceptable to reduce the force coefficients, C_f, for the additional projected area caused by ice on both round and flat members by the factor for rounded members in Note 3 of Figure 29.4-3.

10.5.5 Wind on Ice-Covered Guys and Cables The force coefficient, C_f, (as defined in Chapter 29) for ice-covered guys and cables shall be 1.2.

10.6 DESIGN TEMPERATURES FOR FREEZING RAIN

The design temperatures for ice, and wind-on-ice, caused by freezing rain shall be either the concurrent temperature for the site shown in Figures 10.6-1 and 10.6-2 or 32 °F (0° C), whichever gives the maximum load effect. The temperature for Hawaii shall be 32 °F (0 °C). For temperature-sensitive structures, the load shall include the effect of temperature change from everyday conditions to the design temperature for ice and wind on ice. These temperatures shall be used with nominal ice thicknesses for all Risk Categories.

10.7 PARTIAL LOADING

The full intensity of the ice load applied to a portion of a structure or member shall be accounted for when it produces a critical load effect. It is permitted to consider this to be a static load.

10.8 DESIGN PROCEDURE

1. The nominal ice thickness, t, the concurrent wind speed, V_c, and the concurrent temperature for the site shall be determined from Figures 10.4-2 through 10.4-5, 10.5-1, 10.5-2, 10.6-1, and 10.6-2 or a site-specific study.
2. The topographic factor for the site, K_{zt}, shall be determined in accordance with Section 10.4.4.
3. The height factor, f_z, shall be determined in accordance with Section 10.4.3 for each design segment of the structure.
4. The design ice thickness, t_d, shall be determined in accordance with Section 10.4.5, Equation (10.4-5).
5. The ice load shall be calculated for the design ice thickness, t_d, in accordance with Section 10.4.1.
6. The velocity pressure, q_z, for wind speed, V_c, shall be determined in accordance with Section 29.3.
7. The wind force coefficients, C_f, shall be determined in accordance with Section 10.5.
8. The gust effect factor shall be determined in accordance with Section 26.11.
9. The design wind force shall be determined in accordance with Chapter 29.
10. The iced structure shall be analyzed for the load combinations in either Section 2.3 or 2.4.

10.9 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

CHAPTER 11
SEISMIC DESIGN CRITERIA

11.1 GENERAL

11.1.1 Purpose Chapter 11 presents criteria for the design and construction of buildings and other structures subject to earthquake ground motions. The specified earthquake loads are based on postelastic energy dissipation in the structure. Because of this fact, the requirements for design, detailing, and construction shall be satisfied, even for structures and members for which load combinations that do not include earthquake loads indicate larger demands than combinations that include earthquake loads.

11.1.2 Scope Every structure and portion thereof, including nonstructural components, shall be designed and constructed to resist the effects of earthquake motions as prescribed by the seismic requirements of this standard. Certain nonbuilding structures, as described in Chapter 15, are also within the scope and shall be designed and constructed in accordance with the requirements of Chapter 15. The following structures are exempt from the seismic requirements of this standard:

1. Detached one- and two-family dwellings that are located where the mapped, short period, spectral response acceleration parameter, S_S, is less than 0.4 or where the seismic design category determined in accordance with Section 11.6 is A, B, or C.
2. Detached one- and two-family wood-frame dwellings not included in Exemption 1 with not more than two stories above grade plane, satisfying the limitations of and constructed in accordance with the IRC.
3. Agricultural storage structures that are intended only for incidental human occupancy.
4. Nonbuilding structures that require special consideration of their response characteristics and environment that are not addressed in Chapter 15 and for which other regulations provide seismic criteria, such as vehicular bridges, electrical transmission towers, hydraulic structures, buried utility lines and their appurtenances, and nuclear reactors.
5. Piers and wharves that are not accessible to the general public.

11.1.3 Applicability Structures and their nonstructural components shall be designed and constructed in accordance with the requirements of the following chapters based on the type of structure or component:

Buildings: Chapter 12
Nonbuilding structures: Chapter 15
Nonstructural components: Chapter 13
Seismically isolated structures: Chapter 17
Structures with damping systems: Chapter 18

Buildings whose purpose is to enclose equipment or machinery and whose occupants are engaged in maintenance or monitoring of that equipment, machinery, or their associated processes shall be permitted to be classified as nonbuilding structures designed and detailed in accordance with Section 15.5 of this standard.

11.1.4 Alternate Materials and Methods of Construction Alternate materials and methods of construction to those prescribed in the seismic requirements of this standard shall not be used unless approved by the Authority Having Jurisdiction. Substantiating evidence shall be submitted demonstrating that the proposed alternate will be at least equal in strength, durability, and seismic resistance for the purpose intended.

11.1.5 Quality Assurance Quality assurance for seismic force-resisting systems and other designated seismic systems defined in Section 13.2.2 shall be provided in accordance with the requirements of the Authority Having Jurisdiction.

Where the Authority Having Jurisdiction has not adopted quality assurance requirements, or where the adopted requirements are not applicable to the seismic force-resisting system or designated seismic systems as described in Section 13.2.2, the registered design professional in responsible charge of designing the seismic force-resisting system or other designated seismic systems shall submit a quality assurance plan to the Authority Having Jurisdiction for approval. The quality assurance plan shall specify the quality assurance program elements to be implemented.

11.2 DEFINITIONS

The following definitions apply only to the seismic provisions of Chapters 11 through 22 of this standard.

ACTIVE FAULT: A fault determined to be active by the Authority Having Jurisdiction from properly substantiated data (e.g., most recent mapping of active faults by the US Geological Survey).

ADDITION: An increase in building area, aggregate floor area, height, or number of stories of a structure.

ALTERATION: Any construction or renovation to an existing structure other than an addition.

APPENDAGE: An architectural component such as a canopy, marquee, ornamental balcony, or statuary.

APPROVAL: The written acceptance by the Authority Having Jurisdiction of documentation that establishes the qualification of a material, system, component, procedure, or person to fulfill the requirements of this standard for the intended use.

@seismicisolation
@seismicisolation

ATTACHMENTS: Means by which nonstructural components or supports of nonstructural components are secured or connected to the seismic force-resisting system of the structure. Such attachments include anchor bolts, welded connections, and mechanical fasteners.

BASE: The level at which the horizontal seismic ground motions are considered to be imparted to the structure.

BASE SHEAR: Total design lateral force or shear at the base.

BOUNDARY ELEMENTS: Portions along wall and diaphragm edges for transferring or resisting forces. Boundary elements include chords and collectors at diaphragm and shear wall perimeters, edges of openings, discontinuities, and reentrant corners.

BUILDING: Any structure whose intended use includes shelter of human occupants.

CANTILEVERED COLUMN SYSTEM: A seismic force-resisting system in which lateral forces are resisted entirely by columns acting as cantilevers from the base.

CHARACTERISTIC EARTHQUAKE: An earthquake assessed for an active fault having a magnitude equal to the best estimate of the maximum magnitude capable of occurring on the fault but not less than the largest magnitude that has occurred historically on the fault.

COLLECTOR (DRAG STRUT, TIE, DIAPHRAGM STRUT): A diaphragm or shear wall boundary element parallel to the applied load that collects and transfers diaphragm shear forces to the vertical elements of the seismic force-resisting system or distributes forces within the diaphragm or shear wall.

COMPONENT: A part of an architectural, electrical, or mechanical system.

Component, Flexible: Nonstructural component that has a fundamental period greater than 0.06 s.

Component, Nonstructural: A part of an architectural, mechanical, or electrical system within or without a building or nonbuilding structure.

Component, Rigid: Nonstructural component that has a fundamental period less than or equal to 0.06 s.

Component, Rugged: A nonstructural component that has been shown to consistently function after design earthquake level or greater seismic events (based on past earthquake experience data or past seismic testing) when adequately anchored or supported. The classification of a nonstructural component as rugged shall be based on a comparison of the specific component with components of similar strength and stiffness. Common examples of rugged components are AC motors, compressors, and base-mounted horizontal pumps.

CONCRETE:

Plain Concrete: Concrete that is either unreinforced or contains less reinforcement than the minimum amount specified in ACI 318 for reinforced concrete.

Reinforced Concrete: Prestressed or nonprestressed concrete reinforced with no less reinforcement than the minimum amount required by ACI 318 and designed on the assumption that the two materials act together in resisting forces.

CONSTRUCTION DOCUMENTS: The written, graphic, electronic, and pictorial documents describing the design, locations, and physical characteristics of the project required to verify compliance with this standard.

COUPLING BEAM: A beam that is used to connect adjacent concrete wall elements to make them act together as a unit to resist lateral loads.

DEFORMABILITY: The ratio of the ultimate deformation to the limit deformation.

High-Deformability Element: An element whose deformability is not less than 3.5 where subjected to four fully reversed cycles at the limit deformation.

Limited-Deformability Element: An element that is neither a low-deformability nor a high-deformability element.

Low-Deformability Element: An element whose deformability is 1.5 or less.

DEFORMATION:

Limit Deformation: Two times the initial deformation that occurs at a load equal to 40% of the maximum strength.

Ultimate Deformation: The deformation at which failure occurs and that shall be deemed to occur if the sustainable load reduces to 80% or less of the maximum strength.

DESIGN EARTHQUAKE: The earthquake effects that are two-thirds of the corresponding risk-targeted maximum considered earthquake (MCE_R).

DESIGN EARTHQUAKE DISPLACEMENT: *See* DISPLACEMENT AND DRIFT. *See* DISPLACEMENT AND DRIFT. *See* **DESIGN STORY DRIFT**.

DESIGN EARTHQUAKE GROUND MOTION: The earthquake ground motions that are two-thirds of the corresponding MCE_R ground motions.

DESIGNATED SEISMIC SYSTEMS: Those nonstructural components that require design in accordance with Chapter 13 and for which the component Importance Factor, I_p, is greater than 1.0.

DIAPHRAGM: Roof, floor, or other membrane or bracing system acting to transfer the lateral forces to the vertical resisting elements.

Flexure-Controlled Diaphragm: Diaphragm with a flexural yielding mechanism, which limits the maximum forces that develop in the diaphragm, and a design shear strength or factored nominal shear capacity greater than the shear corresponding to the nominal flexural strength.

Shear-Controlled Diaphragm: Diaphragm that does not meet the requirements of a flexure-controlled diaphragm.

Transfer Forces, Diaphragm: Forces that occur in a diaphragm caused by transfer of seismic forces from the vertical seismic force-resisting elements above the diaphragm to other vertical seismic force-resisting elements below the diaphragm because of offsets in the placement of the vertical elements or changes in relative lateral stiffnesses of the vertical elements.

Vertical Diaphragm: *See* WALL: Shear Wall.

DIAPHRAGM BOUNDARY: A location where shear is transferred into or out of the diaphragm element. Transfer is either to a boundary element or to another force-resisting element.

DIAPHRAGM CHORD: A diaphragm boundary element perpendicular to the applied load that is assumed to take axial stresses caused by the diaphragm moment.

DIAPHRAGM DEFORMATION: The relative horizontal displacement of portions of a diaphragm due to strain in the diaphragm elements and not due to deformations of the vertical elements of the seismic-force resisting system or to diaphragm-rotation effects.

DIAPHRAGM-ROTATION EFFECTS: Relative horizontal displacement of portions of a diaphragm due to unequal deformations of the vertical elements of the seismic-force resisting system.

DISPLACEMENT AND DRIFT:

Design Earthquake Displacement: The displacement at a given location of the structure corresponding to the Design Earthquake.

@seismicisolation

Design Story Drift: The story drift corresponding to the Design Earthquake, taken at a representative plan location (center of mass or building perimeter, as required by Section 12.8.6).

Maximum Considered Earthquake Displacement: The displacement at a given location of the structure corresponding to the Risk-Targeted Maximum Considered Earthquake (MCE_R).

Story Drift: The horizontal displacement at the top of the story relative to the bottom of the story at vertically aligned points corresponding to the given loading.

Story Drift Ratio: The story drift divided by the story height, h_{sx}.

DISTRIBUTION SYSTEM: An interconnected system composed primarily of linear components including piping, tubing, conduit, raceways, or ducts. Distribution systems include in-line components such as valves, in-line suspended pumps, and mixing boxes.

ELEMENT ACTION: Element axial, shear, or flexural behavior.

Critical Action: An action, failure of which would result in the collapse of multiple bays or multiple stories of the building or would result in a significant reduction in the structure's seismic resistance.

Deformation-Controlled Action: Element actions for which reliable inelastic deformation capacity is achievable without critical strength decay.

Force-Controlled Action: Any element actions modeled with linear properties and element actions not classified as deformation-controlled.

Noncritical Actions: An action, failure of which would not result in either collapse or significant loss of the structure's seismic resistance.

Ordinary Action: An action, failure of which would result in only local collapse, comprising not more than one bay in a single story, and would not result in a significant reduction of the structure's seismic resistance.

ENCLOSURE: An interior space surrounded by walls.

EQUIPMENT SUPPORT: Those structural members or assemblies of members or manufactured elements, including braces, frames, legs, lugs, snuggers, hangers, or saddles, that transmit gravity loads and operating loads between the equipment and the structure.

Equipment Support Structures and Platforms: Assemblies of members or manufactured elements other than integral supports, including, but not limited to, moment frames, braced frames, skids, legs longer than 24 in. (600 mm), or walls that support one or more nonstructural components or systems.

Distribution System Support: Members that provide vertical or lateral seismic resistance for distribution systems, including but not limited to, hangers, braces, pipe racks, and trapeze assemblies.

Equipment Support, Integral: Assemblies of members or manufactured elements and their associated attachments and base plates that provide vertical or lateral support for nonstructural components, are directly connected to both the nonstructural component and the attachment to the structure or foundation, and where the nonstructural component acts as part of the lateral force resisting system of the equipment support. Integral equipment supports include but are not limited to legs less than or equal to 24 in. (600 mm) in length, lugs, skirts, and saddles.

FLEXIBLE CONNECTIONS: Those connections between equipment components that permit rotational and/or translational movement without degradation of performance. Examples include universal joints, bellows expansion joints, and flexible metal hose.

FOUNDATION GEOTECHNICAL CAPACITY: The maximum pressure or strength design capacity of a foundation based on the supporting soil, rock, or controlled low-strength material.

FOUNDATION STRUCTURAL CAPACITY: The design strength of foundations or foundation components as provided by adopted material standards and as altered by the requirements of this standard.

FRAME:

Braced Frame: An essentially vertical truss, or its equivalent, of the concentric or eccentric type that is provided in a building frame system or dual system to resist seismic forces.

Concentrically Braced Frame (CBF): A braced frame in which the members are subjected primarily to axial forces. CBFs are categorized as ordinary concentrically braced frames (OCBFs) or special concentrically braced frames (SCBFs).

Eccentrically Braced Frame (EBF): A diagonally braced frame in which at least one end of each brace frames into a beam a short distance from a beam-column or from another diagonal brace.

Moment Frame: A frame in which members and joints resist lateral forces by flexure and along the axis of the members. Moment frames are categorized as intermediate moment frames (IMFs), ordinary moment frames (OMFs), and special moment frames (SMFs).

STRUCTURAL SYSTEM:

Building Frame System: A structural system with an essentially complete space frame providing support for vertical loads. Seismic force resistance is provided by shear walls or braced frames.

Dual System: A structural system with an essentially complete space frame providing support for vertical loads. Seismic force resistance is provided by moment-resisting frames and shear walls or braced frames as prescribed in Section 12.2.5.1.

Shear Wall–Frame Interactive System: A structural system that uses combinations of ordinary reinforced concrete shear walls and ordinary reinforced concrete moment frames designed to resist lateral forces in proportion to their rigidities considering interaction between shear walls and frames on all levels.

Space Frame System: A 3-D structural system composed of interconnected members, other than bearing walls, that is capable of supporting vertical loads and, where designed for such an application, is capable of providing resistance to seismic forces.

FRICTION CLIP: A device that relies on friction to resist applied loads in one or more directions to anchor a nonstructural component. Friction is provided mechanically and is not due to gravity loads.

GLAZED CURTAIN WALL: A nonbearing wall that extends beyond the edges of building floor slabs and includes a glazing material installed in the curtain wall framing.

GLAZED STOREFRONT: A nonbearing wall that is installed between floor slabs, typically including entrances, and includes a glazing material installed in the storefront framing.

GRADE PLANE: A horizontal reference plane representing the average of finished ground level adjoining the structure at all exterior walls. Where the finished ground level slopes away from the exterior walls, the grade plane is established by the lowest points within the area between the structure and the property line or, where the property line is more than 6 ft (1,829 mm) from the structure, between the structure and points 6 ft (1,829 mm) from the structure.

HEATING, VENTILATING, AIR-CONDITIONING, AND REFRIGERATION (HVACR): The equipment, distribution systems, and terminals, excluding interconnecting piping and ductwork that provide, either collectively or individually, the processes of heating, ventilating, air-conditioning, or refrigeration to a building or portion of a building.

@seismicisolation

INSPECTION, SPECIAL: The observation of the work by a special inspector to determine compliance with the approved construction documents and these standards in accordance with the quality assurance plan.

Continuous Special Inspection: The full-time observation of the work by a special inspector who is present in the area where work is being performed.

Periodic Special Inspection: The part-time or intermittent observation of the work by a special inspector who is present in the area where work has been or is being performed.

INSPECTOR, SPECIAL: A person approved by the Authority Having Jurisdiction to perform special inspection, and who shall be identified as the owner's inspector.

INVERTED PENDULUM-TYPE STRUCTURES: Structures in which more than 50% of the structure's mass is concentrated at the top of a slender, cantilevered structure and in which the stability of the mass at the top of the structure relies on rotational restraint to the top of the cantilevered element.

JOINT: The geometric volume common to intersecting members.

LIGHT-FRAME CONSTRUCTION: A method of construction where the structural assemblies (e.g., walls, floors, ceilings, and roofs) are primarily formed by a system of repetitive wood or cold-formed steel framing members or subassemblies of these members (e.g., trusses).

LONGITUDINAL REINFORCEMENT RATIO: Area of longitudinal reinforcement divided by the cross-sectional area of the concrete.

MAXIMUM CONSIDERED EARTHQUAKE DISPLACEMENT: *See* DISPLACEMENT AND DRIFT

MAXIMUM CONSIDERED EARTHQUAKE (MCE) GROUND MOTION: The most severe earthquake effects considered by this standard, more specifically defined in the following two terms:

Maximum Considered Earthquake Geometric Mean (MCE_G) Peak Ground Acceleration: The most severe earthquake effects considered by this standard determined for geometric mean peak ground acceleration and without adjustment for targeted risk. The MCE_G peak ground acceleration adjusted for site effects (PGA_M) is used in this standard for evaluation of liquefaction, lateral spreading, seismic settlements, and other soil-related issues. In this standard, general procedures for determining PGA_M are provided in Section 11.8.3; site-specific procedures are provided in Section 21.5.

Risk-Targeted Maximum Considered Earthquake (MCE_R) Ground Motion Response Acceleration: The most severe earthquake effects considered by this standard determined for the orientation that results in the largest maximum response to horizontal ground motions and with adjustment for targeted risk. In this standard, general procedures for determining the MCE_R ground motion values are provided in Section 11.4.4; site-specific procedures are provided in Sections 21.1 and 21.2.

MECHANICALLY ANCHORED TANKS OR VESSELS: Tanks or vessels provided with mechanical anchors to resist overturning moments.

NONBUILDING STRUCTURE: A structure, other than a building, constructed of a type included in Chapter 15 and within the limits of Section 15.1.1.

NONBUILDING STRUCTURE SIMILAR TO A BUILDING: A nonbuilding structure that is designed and constructed in a manner similar to buildings, responds to strong ground motion in a fashion similar to buildings, and has a basic lateral and vertical seismic force-resisting system conforming to one of the types indicated in Table 12.2-1 or 15.4-1.

OPEN-TOP TANK: A tank without a fixed roof or cover, floating cover, gas holder cover, or dome.

ORTHOGONAL: In two horizontal directions, at 90 degrees to each other.

OWNER: Any person, agent, firm, or corporation that has a legal or equitable interest in a property.

P-DELTA EFFECT: The secondary effect on shears and moments of structural members caused by the action of the vertical loads induced by horizontal displacement of the structure resulting from various loading conditions.

PARTITION: A nonstructural interior wall that spans horizontally or vertically from support to support. The supports may be the basic building frame, subsidiary structural members, or other portions of the partition system.

PILE: Deep foundation element, which includes piers, caissons, and piles.

PILE CAP: Foundation elements to which piles are connected, including grade beams and mats.

PREMANUFACTURED MODULAR MECHANICAL AND ELECTRICAL SYSTEM: A prebuilt, fully or partially enclosed assembly of mechanical and electrical components.

REGISTERED DESIGN PROFESSIONAL: An architect or engineer registered or licensed to practice professional architecture or engineering, as defined by the statutory requirements of the professional registration laws of the state in which the project is to be constructed.

REINFORCED CONCRETE DUCTILE COUPLED WALL: A seismic force-resisting system as defined in ACI 318 Section 2.3 and complying with ACI 318 Section 18.10.9.

SEISMIC DESIGN CATEGORY: A classification assigned to a structure based on its Risk Category and the severity of the design earthquake ground motion at the site, as defined in Section 11.4.

SEISMIC FORCE-RESISTING SYSTEM: That part of the structural system that has been considered in the design to provide the required resistance to the seismic forces prescribed herein.

SEISMIC FORCES: The assumed forces prescribed herein, related to the response of the structure to earthquake motions, to be used in the design of the structure and its components.

SELF-ANCHORED TANKS OR VESSELS: Tanks or vessels that are stable under design overturning moment without the need for mechanical anchors to resist uplift.

SHEAR PANEL: A floor, roof, or wall element sheathed to act as a shear wall or diaphragm.

SITE CLASS: A classification assigned to a site based on the types of soils present and their engineering properties, as defined in Chapter 20.

STORAGE RACKS, STEEL: A framework or assemblage, comprised of cold-formed or hot-rolled steel structural members, intended for storage of materials, including, but not limited to, pallet storage racks, selective racks, movable-shelf racks, rack-supported systems, automated storage and retrieval systems (stacker racks), push-back racks, pallet-flow racks, case-flow racks, pick modules, and rack-supported platforms. Other types of racks, such as drive-in or drive-through racks, cantilever racks, portable racks, or racks made of materials other than steel, are not considered steel storage racks for the purpose of this standard.

STORAGE RACKS, STEEL CANTILEVERED: A framework or assemblage comprised of cold-formed or hot-rolled steel structural members, primarily in the form of vertical columns, extended bases, horizontal arms projecting from the faces of the columns, and longitudinal (down-aisle) bracing between columns. There may be shelf beams between the arms, depending

@seismicisolation

on the products being stored; this definition does not include other types of racks such as pallet storage racks, drive-in racks, drive-through racks, or racks made of materials other than steel.

STORY: The portion of a structure between the tops of two successive floor surfaces and, for the topmost story, from the top of the floor surface to the top of the roof surface.

STORY ABOVE GRADE PLANE: A story in which the floor or roof surface at the top of the story is more than 6 ft (1,829 mm) above grade plane or is more than 12 ft (3,658 mm) above the finished ground level at any point on the perimeter of the structure.

STORY DRIFT: *See* DISPLACEMENT AND DRIFT

STORY SHEAR: The summation of design lateral seismic forces at levels above the story under consideration.

STRENGTH:

Design Strength: Nominal strength multiplied by a strength reduction factor, ϕ.

Nominal Strength: Strength of a member or cross section calculated in accordance with the requirements and assumptions of the strength design methods of this standard (or the reference documents) before application of any strength-reduction factors.

Required Strength: Strength of a member, cross section, or connection required to resist factored loads or related internal moments and forces in such combinations as stipulated by this standard.

STRUCTURAL HEIGHT: The vertical distance from the base to the highest level of the seismic force-resisting system of the structure. For pitched or sloped roofs, the structural height is from the base to the average height of the roof.

STRUCTURAL OBSERVATIONS: The visual observations to determine that the seismic force-resisting system is constructed in general conformance with the construction documents.

STRUCTURE: That which is built or constructed and limited to buildings and nonbuilding structures as defined herein.

SUBDIAPHRAGM: A portion of a diaphragm used to transfer wall anchorage forces to diaphragm crossties.

SUPPORTS: Those members, assemblies of members, or manufactured elements, including braces, frames, legs, lugs, snubbers, hangers, saddles, or struts, and associated fasteners that transmit loads between nonstructural components and their attachments to the structure.

TESTING AGENCY: A company or corporation that provides testing and/or inspection services.

TRUSSED TOWER: A lattice-type structure, freestanding or guyed, which supports static equipment such as chimneys, stacks, lights, or other lightweight components.

USGS SEISMIC DESIGN GEODATABASE: A US Geological Survey (USGS) database of geocoded values of seismic design parameters S_S, S_1, S_{MS}, S_{M1}, and PGA_M and geocoded sets of multi-period 5%-damped risk-targeted maximum considered earthquake (MCE_R) response spectra.

User Note: The USGS Seismic Design Geodatabase is intended to be accessed through a USGS Seismic Design Web Service that allows the user to specify the site location, by latitude and longitude, and the site class to obtain the seismic design data. The USGS web service spatially interpolates between the gridded data of the USGS geodatabase. Both the USGS geodatabase and the USGS web service can be accessed at https://doi.org/10.5066/F7NK3C76. The USGS Seismic Design Geodatabase is available at the ASCE 7 Hazard Tool https://asce7hazardtool.online/ or an approved equivalent.

VENEERS: Facings or ornamentation of brick, concrete, stone, tile, or similar materials attached to a backing.

WALL: A component that has a slope of 60 degrees or greater with the horizontal plane used to enclose or divide space.

Bearing Wall: Any wall meeting either of the following classifications:

1. Any metal or wood stud wall that supports more than 100 lb per linear ft (1,459 N/m) of vertical load in addition to its own weight.
2. Any concrete or masonry wall that supports more than 200 lb per linear ft (2,919 N/m) of vertical load in addition to its own weight.

Light Frame Wall: A wall with wood or steel studs.

Light Frame Wood Shear Wall: A wall constructed with wood studs and sheathed with material rated for shear resistance.

Nonbearing Wall: Any wall that is not a bearing wall.

Nonstructural Wall: A wall other than a bearing wall or shear wall.

Shear Wall (Vertical Diaphragm): A wall, bearing or nonbearing, designed to resist lateral forces acting in the plane of the wall (sometimes referred to as a "vertical diaphragm").

Structural Wall: A wall that meets the definition for bearing wall or shear wall.

WALL SYSTEM:

BEARING: A structural system with bearing walls providing support for all or major portions of the vertical loads. Shear walls or braced frames provide seismic force resistance.

WOOD STRUCTURAL PANEL: A wood-based panel product that meets the requirements of DOC PS1 or DOC PS2 and is bonded with a waterproof adhesive. Included under this designation are plywood, oriented strand board, and composite panels.

11.3 SYMBOLS

The unit dimensions used with the items covered by the symbols shall be consistent throughout except where specifically noted. Symbols presented in this section apply only to the seismic provisions of Chapters 11 through 22 in this standard.

A_0 = Area of the load-carrying foundation, ft^2 (m^2)

A_{ch} = Cross-sectional area, $in.^2$ (mm^2), of a structural member measured out-to-out of transverse reinforcement

A_{sh} = Total cross-sectional area of hoop reinforcement, $in.^2$ (mm^2), including supplementary crossties, having a spacing of s_h and crossing a section with a core dimension of h_c

A_{vd} = Required area of leg of diagonal reinforcement, $in.^2$ (mm^2)

A_x = Torsional amplification factor (Section 12.8.4.3)

a_i = Acceleration at level i obtained from a modal analysis (Section 13.3.1)

a_i = the maximum acceleration at level i obtained from the nonlinear response history analysis at the Design Earthquake ground motion

b_p = Width of the rectangular glass panel

C_{AR} = Component resonance ductility factor that converts the peak floor or ground acceleration into the peak component acceleration as determined in Section 13.3.1.3

C_d = Deflection amplification factor as given in Table 12.2-1, 15.4-1, or 15.4-2

C_{dX} = Deflection amplification factor in the X direction (Section 12.9.2.5)

C_{dY} = Deflection amplification factor in the Y direction (Section 12.9.2.5)

$C_{s\text{-diaph}}$ = Seismic response coefficient for design of diaphragms using the alternative diaphragm design method of Section 12.10.4

@seismicisolation

$C_{d\text{-}diaph}$ = Deflection amplification factor for diaphragm deflection (12.10.4)
C_{p0} = Diaphragm design acceleration coefficient at the structure base (Section 12.10.3.2.1)
C_{pi} = Diaphragm design acceleration coefficient at 80% of the structural height above the base, h_n (Section 12.10.3.2.1)
C_{pn} = Diaphragm design acceleration coefficient at the structural height, h_n (Section 12.10.3.2.1)
C_{px} = Diaphragm design acceleration coefficient at level x (Section 12.10.3.2.1)
C_s = Seismic response coefficient determined in Section 12.8.1.1 or 19.3.1 (dimensionless)
C_{s2} = Higher mode seismic response coefficient (Section 12.10.3.2.1)
C_t = Building period coefficient (Section 12.8.2.1)
C_v = Vertical response spectral coefficient as given in Table 11.9-1
C_{vs} = Coefficient of variation of soil shear modulus, defined as the standard deviation divided by the mean (Section 12.13.3)
C_{vx} = Vertical distribution factor as determined in Section 12.8.3
c = Distance from the neutral axis of a flexural member to the fiber of maximum compressive strain, in. (mm)
D = Effect of dead load
D_{clear} = Relative horizontal (drift) displacement, measured over the height of the glass panel under consideration, which causes initial glass-to-frame contact. For rectangular glass panels within a rectangular wall frame, D_{clear} is set forth in Section 13.5.9.1
D_{pI} = Seismic relative displacement (Section 13.3.2)
D_s = Total depth of stratum in Equation (19.3-4), ft (m)
d_c = Total thickness of cohesive soil layers in the top 100 ft (30 m), ft (m) (Section 20.4.3)
d_i = Thickness of any soil or rock layer i [between 0 and 100 ft (0 and 30 m)]; see Section 20.4.1
d_S = Total thickness of cohesionless soil layers in the top 100 ft (30 m), ft (m) (Section 20.4.2)
E = Effect of horizontal and vertical earthquake-induced forces (Section 12.4)
E_{cl} = Capacity-limited horizontal seismic load effect, equal to the maximum force that can develop in the element as determined by a rational, plastic mechanism analysis
F_i, F_n, F_x = Portion of the seismic base shear, V, induced at level i, n, or x, respectively, as determined in Section 12.8.3
F_{md} = Factor to convert the geometric mean spectral ordinate to a maximum direction spectral ordinate
F_p = Seismic force acting on a component of a structure as determined in Sections 12.11.1 and 13.3.1
F_{px} = Diaphragm seismic design force at level x
f'_c = Specified compressive strength of concrete used in design
f'_s = Ultimate tensile strength of the bolt, stud, or insert leg wires, psi (MPa). For ASTM A307 bolts or ASTM A108 studs, it is permitted to be assumed to be 60,000 psi (415 MPa)
f_y = Specified yield strength of reinforcement, psi (MPa)
f_{yh} = Specified yield strength of the special lateral reinforcement, psi (kPa)
$G = \gamma v_s^2/g$ = Average shear modulus for the soils beneath the foundation at large strain levels, lb/ft^2 (Pa)
$G_0 = \gamma v_{s0}^2/g$ = Average shear modulus for the soils beneath the foundation at small strain levels, lb/ft^2 (Pa)
g = Acceleration due to gravity
H = Thickness of soil
H_f = Factor for force amplification as a function of height in the structure as determined in Section 13.3.1.1
h = Height of a shear wall measured as the maximum clear height from top of foundation to bottom of diaphragm framing above, or the maximum clear height from top of diaphragm to bottom of diaphragm framing above
h = Average roof height of structure with respect to the base (Chapter 13)
h^* = Effective height of the building, ft (m), as determined in Chapter 19
h_c = Core dimension of a component measured to the outside of the special lateral reinforcement, in. (mm)
h_i, h_x = Height above the base to level i or x, respectively
h_n = Structural height as defined in Section 11.2
h_p = Height of the rectangular glass panel
h_{sx} = Story height below level $x = (h_x - h_{x-1})$
I_e = Importance Factor as prescribed in Section 11.5.1
I_p = Component Importance Factor as prescribed in Section 13.3.1
i = Building level referred to by a subscript i; $i = 1$ designates the first level above the base
K_p = Stiffness of the component or attachment (Section 13.3.3)
K_{xx}, K_{rr} = Rotational foundation stiffness in Equations (19.3-9) and (19.3-19), ft-lb/degree (N-m/rad)
K_y, K_r = Translational foundational stiffness in Equations (19.3-8) and (19.3-18), lb/in. (N/m)
KL/r = Lateral slenderness ratio of a compression member measured in terms of its effective length, KL, and the least radius of gyration of the member cross section, r
k = Distribution exponent, given in Section 12.8.3
k_a = Coefficient for amplification factor for diaphragm flexibility defined in Sections 12.11.2.1 and 12.14.7.5
L = Overall length of the building at the base in the direction being analyzed, ft (m)
L_{diaph} = Span in feet of the horizontal diaphragm or diaphragm segment being considered, measured between vertical elements or collectors that provide support to the diaphragm or diaphragm segment (Section 12.10.4)
M_t = Torsional moment resulting from eccentricity between the locations of the center of mass and the center of rigidity (Section 12.8.4.1)
M_{ta} = Accidental torsional moment as determined in Section 12.8.4.2
m = Subscript denoting the mode of vibration under consideration; $m = 1$ for the fundamental mode
N = Standard penetration resistance per ASTM D1586
N = Number of stories above the base (Section 12.8.2.1)
$\overline{N}$ = Average field standard penetration resistance for the top 100 ft (30 m) (Sections 20.3.3 and 20.4.2)
$\overline{N}_{ch}$ = Average standard penetration resistance for cohesionless soil layers for the top 100 ft (30 m) (Sections 20.3.3 and 20.4.2)
N_i = Standard penetration resistance of any soil or rock layer i [between 0 and 100 ft (0 and 30 m)]; see Section 20.4.2
n = Designation for the level that is uppermost in the main portion of the building
PGA_G = Lower-bound limit on deterministic maximum considered earthquake geometric mean peak ground acceleration (Table 21.2-1)

@seismicisolation
@seismicisolation

PGA_M = Mapped MCE_G peak ground acceleration as defined in Section 11.8.3

PI = Plasticity index per ASTM D4318

P_x = Total unfactored vertical design load at and above level x, for use in Section 12.8.7

Q_E = Effect of horizontal seismic (earthquake-induced) forces

R = Response modification coefficient as given in Tables 12.2-1, 12.14-1, 15.4-1, and 15.4-2

R_{diaph} = Response modification coefficient for design of diaphragms using the alternative diaphragm design method of Section 12.10.4

R_{po} = Component strength factor as determined in Section 13.3.1.4

R_μ = Structure ductility reduction factor as determined in Section 13.3.1.2

R_s = Diaphragm design force reduction factor (Section 12.10.3.5)

R_X = Response modification coefficient in the X direction (Section 12.9.2.5)

R_Y = Response modification coefficient in the Y direction (Section 12.9.2.5)

S_1 = MCE_R, 5% damped, spectral response acceleration parameter at a period of 1 s for Site Class BC site conditions as determined in accordance with Section 11.4.3

S_a = 5% damped design spectral response acceleration parameter at any period as defined in Section 11.4.5

S_{aM} = Site-specific, 5% damped, MCE_R spectral response acceleration parameter at any period

S_{av} = 5% damped, design vertical response spectral acceleration parameter at any period as determined in accordance with Section 11.9.3

S_{aMv} = 5% damped, MCE_R vertical response spectral acceleration parameter at any period as determined in accordance with Section 11.9.2

S_{D1} = Design, 5% damped, spectral response acceleration parameter at a period of 1 s as defined in Section 11.4.4

S_{DpS} = Design, 5% damped, spectral response acceleration parameter at short periods as defined in Section 11.4.4

S_{M1} = MCE_R, 5% damped, spectral response acceleration parameter at a period of 1 s adjusted for site class effects as defined in determined in accordance with Section 11.4.3

S_{MS} = MCE_R, 5% damped, spectral response acceleration parameter at short periods adjusted for site class effects as determined in accordance with Section 11.4.3

S_S = MCE_R, 5% damped, spectral response acceleration parameter at a period of 0.2 s for Site Class BC site conditions as determined in accordance with Section 11.4.3

s_h = Spacing of special lateral reinforcement, in. (mm)

s_u = Undrained shear strength (Section 20.4.3)

$\bar{s}_u$ = Average undrained shear strength in top 100 ft (30 m); see Sections 20.3.3 and 20.4.3, ASTM D2166, or ASTM D2850

s_{ui} = Undrained shear strength of any cohesive soil layer i [between 0 and 100 ft (0 and 30 m)]; see Section 20.4.3

T = Fundamental period of the building

T_0 = $0.2S_{D1}/S_{DS}$

$\tilde{T}$ = Fundamental period as determined in Chapter 19

T_a = Approximate fundamental period of the building as determined in Section 12.8.2

T_{diaph} = Period of diaphragm for design of diaphragm using the alternative diaphragm design method of Section 12.10.4

T_L = Long-period transition period(s) shown in Figures 22-14 through 22-17

T_{lower} = Period of vibration at which 90% of the actual mass has been recovered in each of the two orthogonal directions of response (Section 12.9.2). The mathematical model used to compute T_{lower} shall not include accidental torsion and shall include P-delta effects.

T_p = Fundamental period of the component and its attachment (Section 13.3.3)

T_S = S_{D1}/S_{DS}

T_{upper} = Larger of the two orthogonal fundamental periods of vibration (Section 12.9.2). The mathematical model used to compute T_{upper} shall not include accidental torsion and shall include P-delta effects

TIR = Torsional Irregularity Ratio defined in Section 12.3.2.1.1

T_v = Vertical period of vibration

V = Total design lateral force or shear at the base

V_{EX} = Maximum absolute value of elastic base shear computed in the X direction among all three analyses performed in that direction (Section 12.9.2.5)

V_{EY} = Maximum absolute value of elastic base shear computed in the Y direction among all three analyses performed in that direction (Section 12.9.2.5)

V_{IX} = Inelastic base shear in the X direction (Section 12.9.2.5)

V_{IY} = Inelastic base shear in the Y direction (Section 12.9.2.5)

V_t = Design value of the seismic base shear as determined in Section 12.9.1.4.1

V_X = Equivalent lateral force (ELF) base shear in the X direction (Section 12.9.2.5)

V_x = Seismic design shear in story x as determined in Section 12.8.4

V_Y = Equivalent lateral force (ELF) base shear in the Y direction (Section 12.9.2.5)

$\tilde{V}$ = Reduced base shear accounting for the effects of soil structure interaction as determined in Section 19.3.1

$\tilde{V}_1$ = Portion of the reduced base shear, $\tilde{V}_1$, contributed by the fundamental mode, kip (kN) (Section 19.3)

ΔV = Reduction in V as determined in Section 19.3.1, kip (kN)

ΔV_1 = Reduction in V_1 as determined in Section 19.3.1, kip (kN)

v_s = Shear wave velocity, in ft/s (m/s), at small shear strains (greater than 10^{-3}% strain); see Section 19.2.1

$\bar{v}_s$ = Average shear wave velocity at small shear strains in top 100 ft (30 m) (Sections 20.3.3 and 20.4.1)

v_{si} = Shear wave velocity of any soil or rock layer i [between 0 and 100 ft (0 and 30 m)] (Section 20.4.1)

v_{so} = Average shear wave velocity, ft/s (m/s), for the soils beneath the foundation at small strain levels (Section 19.2.1.1)

W = Effective seismic weight of the building as defined in Section 12.7.2. For calculation of seismic-isolated building period, W is the total effective seismic weight of the building, in kip (kN), as defined in Sections 19.2 and 19.3

@seismicisolation

W = Effective seismic weight of the building, in kip (kN), as defined in Sections 19.2 and 19.3
W_c = Gravity load of a component of the building
W_P = Component operating weight, lb (N)
w_{px} = Weight tributary to the diaphragm at level x
w = Moisture content, in percent, per ASTM D2216
w_i, w_n, w_x = Portion of W that is located at or assigned to level i, n, or x, respectively
x = Level under consideration; $x = 1$ designates the first level above the base
z = Height in structure of point of attachment of component with respect to the base (Section 13.3.1)
z_s = Mode shape factor (Section 12.10.3.2.1)
β = Ratio of shear demand to shear capacity for the story between levels x and $x - 1$
$\overline{\beta}$ = Fraction of critical damping for the coupled structure–foundation system, determined in Section 19.2.1
β_0 = Foundation damping factor as specified in Section 19.2.1.2
Γ_{m1}, Γ_{m2} = First and higher modal contribution factors, respectively (Section 12.10.3.2.1)
γ = Average unit weight of soil, lb/ft^3 (N/m^3)
Δ = Design story drift as determined in Section 12.8.6
Δ_{avg} = Average of the story drifts at the two opposing edges of the building, as defined in Section 12.3.2.1.1
Δ_{max} = Maximum story drift at the building's edge subjected to lateral forces, as defined in Section 12.3.2.1.1
$\Delta_{fallout}$ = Relative seismic displacement (drift) at which glass fallout from the curtain wall, storefront, or partition occurs
Δ_a = Allowable story drift as specified in Section 12.12.1
Δ_{ADVE} = Average drift of adjoining vertical elements of the seismic force-resisting system over the story below the diaphragm under consideration, under tributary lateral load equivalent to that used in the computation of δ_{MDD} in Figure 12.3-1, in. (mm)
δ_{DE} = Design earthquake displacement as determined in Section 12.8.6
δ_{di} = Displacement due to diaphragm deformation corresponding to the design earthquake including Section 12.10 diaphragm forces (Section 12.8.6)
δ_e = Elastic displacement computed under design earthquake forces (Section 12.8.6)
δ_{MCE} = Maximum Considered Earthquake Displacement as determined in Section 12.8.6
δ_{MDD} = Computed maximum in-plane deflection of the diaphragm under lateral load, in. (mm) (Figure 12.3-1)
δ_{max} = Maximum displacement at level x considering torsion (Section 12.8.4.3)
δ_M = Maximum inelastic response displacement considering torsion (Section 12.12.3)
δ_{MT} = Total separation distance between adjacent structures on the same property (Section 12.12.3)
δ_{avg} = Average of the displacements at the extreme points of the structure at level x (Section 12.8.4.3)
δ_{xm} = Modal deflection of level x at the center of the mass at and above level x as determined by Section 19.3.2
$\overline{\delta}_x, \overline{\delta}_{x1}$ = Deflection of level x at the center of the mass at and above level x in Equations (19.2-13) and (19.3-3), in. (mm)
θ = Stability coefficient for P-delta effects as determined in Section 12.8.7
ηx = Force scale factor in the X direction (Section 12.9.2.5)
ηy = Force scale factor in the Y direction (Section 12.9.2.5)
ρ = Redundancy factor based on the extent of structural redundancy present in a building, as defined in Section 12.3.4
λ = Time effect factor
Ω_0 = Overstrength factor as defined in Tables 12.2-1, 15.4.-1, and 15.4-2
$\Omega_{0\text{-diaph}}$ = Diaphragm overstrength factor (Section 12.10.4)
Ω_{0p} = The anchorage overstrength factor given in Tables 13.5-1 and 13.6-1

11.4 SEISMIC GROUND MOTION VALUES

11.4.1 Near-Fault Sites Sites satisfying either of the following conditions shall be classified as near fault:

- 9.5 mi (15 km) or less from the surface projection of a known active fault capable of producing M_w7 or larger events, or
- 6.25 mi (10 km) or less from the surface projection of a known active fault capable of producing events M_w6 or larger, but smaller than M_w7.

EXCEPTIONS:

1. Faults with estimated slip rate less than 0.04 in. (1 mm) per year shall not be used to determine whether a site is a near-fault site.
2. The surface projection used in the determination of near-fault site classification shall not include portions of the fault at depths of 6.25 mi (10 km) or greater.

11.4.2 Site Class The site shall be classified as Site Class A, B, BC, C, CD, D, DE, E, or F in accordance with Chapter 20.

11.4.2.1 Default Site Conditions Where the soil properties are not known in sufficient detail to determine the site class, risk-targeted maximum considered earthquake (MCE_R) spectral response accelerations shall be based on the most critical spectral response acceleration at each period of Site Class C, Site Class CD, and Site Class D, unless the Authority Having Jurisdiction determines, based on geotechnical data, that Site Class DE, E, or F soils are present at the site.

11.4.3 Risk-Targeted Maximum Considered Earthquake (MCE_R) Spectral Response Acceleration Parameters Risk-targeted maximum considered earthquake (MCE_R) spectral response acceleration parameters S_S, S_1, S_{MS}, and S_{M1} shall be obtained from the USGS Seismic Design Geodatabase for the applicable site class.

EXCEPTION: Where a site-specific ground motion analysis is performed in accordance with Section 11.4.7, risk-targeted maximum considered earthquake (MCE_R) spectral response acceleration parameters S_{MS} and S_{M1} shall be determined in accordance with Section 21.4 and risk-targeted maximum considered earthquake (MCE_R) spectral response acceleration parameters S_S and S_1 shall be either (1) determined from the site-specific MCE_R response spectrum calculated in accordance with the requirements of Section 21.2.3 assuming Site Class BC site condition or (2) obtained from the USGS Seismic Design Geodatabase.

11.4.4 Design Spectral Acceleration Parameters Design earthquake spectral response acceleration parameters at short periods, S_{DS}, and at 1-s periods, S_{D1}, shall be determined from Equations (11.4-1) and (11.4-2), respectively. Where the simplified alternative design procedure of Section 12.14 is used, the value of S_{DS} shall be determined in accordance with Section 12.14.8.1, and the value for S_{D1} need not be determined.

@seismicisolation
@seismicisolation

$$S_{DS} = \frac{2}{3} S_{MS} \quad (11.4\text{-}1)$$

$$S_{D1} = \frac{2}{3} S_{M1} \quad (11.4\text{-}2)$$

where

S_{MS} = MCE_R, 5%-damped, spectral response acceleration parameter at short periods adjusted for site effects as determined in accordance with Section 11.4.3, and

S_{M1} = MCE_R, 5%-damped, spectral response acceleration parameter at a period of 1 s adjusted for site effects as determined in accordance with Section 11.4.3.

11.4.5 Design Response Spectrum Where a design response spectrum is required by this standard, the design response spectrum shall be determined in accordance with the requirements of Section 11.4.5.1.

EXCEPTIONS:

1. Where a site-specific ground motion analysis is performed in accordance with Section 11.4.7, the design response spectrum shall be determined in accordance with Section 21.3.
2. Where values of the multi-period 5%-damped MCE_R response spectrum are not available from the USGS Seismic Design Geodatabase, the design response spectrum shall be permitted to be determined in accordance with Section 11.4.5.2.

11.4.5.1 Multi-Period Design Response Spectrum The multi-period design response spectrum shall be developed as follows:

1. At discrete values of period, T, equal to 0.0 s, 0.01 s, 0.02 s, 0.03 s, 0.05 s, 0.075 s, 0.1 s, 0.15 s, 0.2 s, 0.25 s, 0.3 s, 0.4 s, 0.5 s, 0.75 s, 1.0 s, 1.5 s, 2.0 s, 3.0 s, 4.0 s, 5.0 s, 7.5 s, and 10 s, the 5%-damped design spectral response acceleration parameter, S_a, shall be taken as 2/3 of the multi-period 5%-damped MCE_R response spectrum from the USGS Seismic Design Geodatabase for the applicable site class.
2. At each response period, T, less than 10 s and not equal to one of the discrete values of period, T, listed in Item 1 above, S_a, shall be determined by linear interpolation between values of S_a, of Item 1 above.
3. At each response period, T, greater than 10 s, S_a, shall be taken as the value of S_a at the period of 10 s of Item 1 above, factored by $10/T$, where the value of T is less than or equal to that of the long-period transition period, T_L, and shall be taken as the value of S_a at the period of 10 s factored by $10T_L/T^2$, where the value of T is greater than that of the long-period transition period, T_L.

11.4.5.2 Two-Period Design Response Spectrum The two-period design response spectrum shall be developed as indicated in Figure 11.4-1 and as follows:

1. For periods less than T_0, the design spectral response acceleration parameter, S_a, shall be taken as given in Equation (11.4-3):

$$S_a = S_{DS}\left(0.4 + 0.6\frac{T}{T_0}\right) \quad (11.4\text{-}3)$$

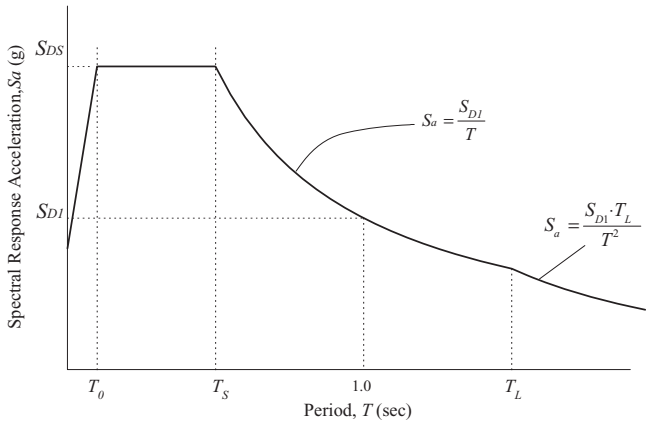

Figure 11.4-1. Two-period design response spectrum.

2. For periods greater than or equal to T_0 and less than or equal to T_S, the design spectral response acceleration parameter, S_a, shall be taken as equal to S_{DS}.
3. For periods greater than T_S and less than or equal to T_L, the design spectral response acceleration parameter, S_a, shall be taken as given in Equation (11.4-4):

$$S_a = \frac{S_{D1}}{T} \quad (11.4\text{-}4)$$

4. For periods greater than T_L, S_a shall be taken as given in Equation (11.4-5):

$$S_a = \frac{S_{D1} T_L}{T^2} \quad (11.4\text{-}5)$$

where

S_{DS} = Design spectral response acceleration parameter at short periods;

S_{D1} = Design spectral response acceleration parameter at a 1 s period;

T = Fundamental period of the structure, S;

$T_0 = 0.2(S_{D1}/S_{DS})$;

$T_S = S_{D1}/S_{DS}$; and

T_L = Long-period transition period(s) shown in Figures 22-14 through 22-17.

11.4.6 Risk-Targeted Maximum Considered Earthquake (MCE_R) Response Spectrum Where an MCE_R response spectrum is required, it shall be determined by multiplying the design response spectrum by 1.5.

11.4.7 Site-Specific Ground Motion Procedures A site response analysis shall be performed in accordance with Section 21.1 for structures on Site Class F sites, unless exempted in accordance with Section 20.3.1.

It shall be permitted to perform a site response analysis in accordance with Section 21.1 and/or a ground motion hazard analysis in accordance with Section 21.2 to determine ground motions for any structure.

When the procedures of either Section 21.1 or 21.2 are used, the design response spectrum shall be determined in accordance with Section 21.3, the design acceleration parameters shall be

@seismicisolation

determined in accordance with Section 21.4, and, if required, the MCE_G peak ground acceleration parameter PGA_M shall be determined in accordance with Section 21.5.

11.5 IMPORTANCE FACTOR AND RISK CATEGORY

11.5.1 Importance Factor An Importance Factor, I_e, shall be assigned to each structure in accordance with Table 1.5-2.

11.5.2 Protected Access for Risk Category IV Where operational access to a Risk Category IV structure is required through an adjacent structure, the adjacent structure shall conform to the requirements for Risk Category IV structures. Where operational access is less than 10 ft (3.048 m) from an interior lot line or another structure on the same lot, protection from potential falling debris from adjacent structures shall be provided by the owner of the Risk Category IV structure.

11.6 SEISMIC DESIGN CATEGORY

Structures shall be assigned a seismic design category in accordance with this section.

Risk Category I, II, or III structures located where the mapped spectral response acceleration parameter at 1-s period, S_1, is greater than or equal to 0.75 shall be assigned to Seismic Design Category E. Risk Category IV structures located where the mapped spectral response acceleration parameter at 1-s period, S_1, is greater than or equal to 0.75 shall be assigned to Seismic Design Category F. All other structures shall be assigned to a seismic design category based on their risk category and the design spectral response acceleration parameters, S_{DS} and S_{D1}, determined in accordance with Section 11.4.4. Each building and structure shall be assigned to the more severe seismic design category in accordance with Table 11.6-1 or 11.6-2, irrespective of the fundamental period of vibration of the structure, T. The provisions in Chapter 19 shall not be used to modify the spectral response acceleration parameters for determining seismic design category.

Where S_1 is less than 0.75, the seismic design category is permitted to be determined from Table 11.6-1 alone where all of the following apply:

1. In each of the two orthogonal directions, the approximate fundamental period of the structure, T_a, determined in accordance with Section 12.8.2.1 is less than $0.8T_s$, where T_s is determined in accordance with Section 11.4.5.
2. In each of two orthogonal directions, the fundamental period of the structure used to calculate the story drift is less than T_s.
3. Equation (12.8-2) is used to determine the seismic response coefficient, C_s.

Table 11.6-1. Seismic Design Category Based on Short-Period Response Acceleration Parameter.

	Risk Category	
Value of S_{DS}	I or II or III	IV
$S_{DS} < 0.167$	A	A
$0.167 \le S_{DS} < 0.33$	B	C
$0.33 \le S_{DS} < 0.50$	C	D
$0.50 \le S_{DS}$	D	D

Table 11.6-2. Seismic Design Category Based on 1 s Period Response Acceleration Parameter.

	Risk Category	
Value of S_{D1}	I or II or III	IV
$S_{D1} < 0.067$	A	A
$0.067 \le S_{D1} < 0.133$	B	C
$0.133 \le S_{D1} < 0.20$	C	D
$0.20 \le S_{D1}$.	D	

4. The diaphragms are rigid in accordance with Section 12.3; or, for diaphragms that are not rigid, the horizontal distance between vertical elements of the seismic force-resisting system does not exceed 40 ft (12.192 m).

Where the alternate simplified design procedure of Section 12.14 is used, the seismic design category is permitted to be determined from Table 11.6-1 alone, using the value of S_{DS} determined in Section 12.14.8.1, except that where S_1 is greater than or equal to 0.75, the seismic design category shall be E.

11.7 DESIGN REQUIREMENTS FOR SEISMIC DESIGN CATEGORY A

Buildings and other structures assigned to Seismic Design Category A need only comply with the requirements of Section 1.4. Nonstructural components in SDC A are exempt from seismic design requirements. In addition, tanks assigned to Risk Category IV shall satisfy the freeboard requirement in Section 15.6.5.1.

11.8 GEOLOGIC HAZARDS AND GEOTECHNICAL INVESTIGATION

11.8.1 Site Limitation for Seismic Design Categories E and F A structure assigned to Seismic Design Category E or F shall not be located where a known potential exists for an active fault to cause rupture of the ground surface at the structure.

11.8.2 Geotechnical Investigation Report Requirements for Seismic Design Categories C through F A geotechnical investigation report shall be provided for a structure assigned to Seismic Design Category C, D, E, or F in accordance with this section. An investigation shall be conducted, and a report shall be submitted that includes an evaluation of the following potential geologic and seismic hazards:

(a) Slope instability,
(b) Liquefaction,
(c) Total and differential settlement, and
(d) Surface displacement caused by faulting or seismically induced lateral spreading or lateral flow.

The report shall contain recommendations for foundation designs or other measures to mitigate the effects of the previously mentioned hazards.

EXCEPTION: Where approved by the Authority Having Jurisdiction, a site-specific geotechnical report is not required where prior evaluations of nearby sites with similar soil conditions provide direction relative to the proposed construction.

@seismicisolation
@seismicisolation

11.8.3 Additional Geotechnical Investigation Report Requirements for Seismic Design Categories D through F The geotechnical investigation report for a structure assigned to Seismic Design Category D, E, or F shall include all of the following, as applicable:

1. The determination of dynamic seismic lateral earth pressures on basement and retaining walls caused by design earthquake ground motions.
2. The potential for liquefaction, seismically-induced permanent ground displacement, and soil strength loss evaluated for site peak ground acceleration, earthquake magnitude, and source characteristics consistent with the MCE_G peak ground acceleration. Peak ground acceleration shall be determined based on either (1) a site-specific study taking into account soil amplification effects as specified in Section 11.4.7 or (2) the value of the MCE_G peak ground acceleration parameter PGA_M from the USGS Seismic Design Geodatabase for the applicable site class.
3. Assessment of potential consequences of liquefaction, seismically-induced permanent ground displacement, and soil strength loss, including, but not limited to, estimation of total and differential settlement, lateral soil movement, lateral soil loads on foundations, reduction in foundation soil-bearing capacity and lateral soil reaction, soil downdrag and reduction in axial and lateral soil reaction for pile foundations, increases in soil lateral pressures on retaining walls, and flotation of buried structures.
4. Discussion of mitigation measures such as, but not limited to, selection of appropriate foundation type and depths, selection of appropriate structural systems to accommodate anticipated displacements and forces, ground stabilization, or any combination of these measures and how they shall be considered in the design of the structure.

11.9 VERTICAL GROUND MOTIONS FOR SEISMIC DESIGN

11.9.1 General If the option to incorporate the effects of vertical seismic ground motions is exercised in lieu of the requirements of Section 12.4.2.2, the requirements of this section are permitted to be used in the determination of the vertical design earthquake ground motions. The requirements of Section 11.9.2 shall only apply to structures in Seismic Design Categories C, D, E, and F located in the conterminous United States at or west of −105 degrees longitude, Alaska, Hawaii, Puerto Rico, US Virgin Islands, Guam and Northern Mariana Islands, and American Samoa. For structures in Seismic Design Categories C, D, E, and F located in the conterminous United States east of −105 degrees longitude, the value of S_{aMv} shall be taken as two-thirds of the value of S_{aM}. The requirements of Section 11.9.3 shall apply to all structures in the Seismic Design Categories C, D, E, and F.

11.9.2 MCE_R **Vertical Response Spectrum** Where a vertical response spectrum is required by this standard and site-specific procedures are not used, the MCE_R vertical response spectral acceleration, S_{aMv}, shall be developed as follows:

1. For vertical periods (T_v) less than or equal to 0.025 s, S_{aMv} shall be determined in accordance with Equation (11.9-1) as follows:

$$S_{aMv} = 0.65C_v(S_{aM}/F_{md}) \tag{11.9-1}$$

2. For vertical periods greater than 0.025 s and less than or equal to 0.05 s, S_{aMv} shall be determined in accordance with Equation (11.9-2) as follows:

$$S_{aMv} = 16_{Cv}(S_{aM}/F_{md})(T_v - 0.025) + 0.65C_v(S_{aM}/F_{md}) \tag{11.9-2}$$

3. For vertical periods greater than 0.05 s and less than or equal to 0.1 s, S_{aMv} shall be determined in accordance with Equation (11.9-3) as follows:

$$S_{aMv} = 1.05C_v(S_{aM}/F_{md}) \tag{11.9-3}$$

4. For vertical periods greater than 0.1 s and less than or equal to 2.0 s, S_{aMv} shall be determined in accordance with Equation (11.9-4) as follows:

$$S_{aMv} = 1.05C_v\left(S_{aM}/F_{md}\right)\left(\frac{0.1}{T_v}\right)^{0.5} \tag{11.9-4}$$

The value of S_{aMv} shall not be less than 0.5 (S_{aM}/F_{md}).

5. For vertical periods greater than 2.0 s, S_{aMv} shall be determined in accordance with Equation (11.9-5) as follows:

$$S_{aMv} = 0.5(S_{aM}/F_{md}) \tag{11.9-5}$$

where

Cv = Is defined in terms of SS in Table 11.9-1;
S_{aM} = MCE_R spectral response acceleration parameter at the same period as S_{aMv};
F_{md} = Factor to convert the geometric mean spectral ordinate to a maximum direction spectral ordinate; and
T_v = Vertical period of vibration.

The maximum-component factor, F_{md}, shall be taken as follows:

$$T_v \le 0.2\,\text{s} : F_{md} = 1.2 \tag{11.9-6}$$

$$0.2 < T_v \le 1.0\,\text{s} : F_{md} = 1.2 + 0.0625(T_v - 0.2) \tag{11.9-7}$$

$$1 < T_v \le 1.0\,\text{s} : F_{md} = 1.25 + 0.05(T_v - 1.0)/9 \tag{11.9-8}$$

In lieu of using the above procedure, a site-specific study is permitted to be performed to obtain S_{aMv}, but the value so

Table 11.9-1. Values of Vertical Coefficient, C_v.

MCE_R Spectral Response Parameter at Short Periods*	Site Classes A, B	Site Class BC	Site Class C	Site Class CD	Site Classes D, DE, E, F
$S_{MS} \ge 2.0$	0.9	1.1	1.3	1.4	1.5

CHAPTER 12
SEISMIC DESIGN REQUIREMENTS FOR BUILDING STRUCTURES

12.1 STRUCTURAL DESIGN BASIS

12.1.1 Basic Requirements The seismic analysis and design procedures to be used in the design of building structures and their members shall be as prescribed in this section. The building structure shall include complete lateral and vertical force-resisting systems capable of providing adequate strength, stiffness, and energy dissipation capacity to withstand the design ground motions within the prescribed limits of deformation and strength demand. The design ground motions shall be assumed to occur along any horizontal direction of a building structure. The adequacy of the structural systems shall be demonstrated through the construction of a mathematical model and evaluation of this model for the effects of design ground motions. The design seismic forces and their distribution over the height of the building structure shall be established in accordance with one of the applicable procedures indicated in Section 12.6, and the corresponding internal forces and deformations in the members of the structure shall be determined. An approved alternative procedure shall not be used to establish the seismic forces and their distribution unless the corresponding internal forces and deformations in the members are determined using a model consistent with the procedure adopted.

EXCEPTION: As an alternative, the simplified design procedures of Section 12.14 are permitted to be used in lieu of the requirements of Sections 12.1 through 12.12, subject to all of the limitations contained in Section 12.14.

12.1.2 Member Design, Connection Design, and Deformation Limit Individual members, including those not part of the seismic force-resisting system, shall be provided with adequate strength to resist the shears, axial forces, and moments determined in accordance with this standard, and connections shall develop the strength of the connected members or the forces indicated in Section 12.1.1. The deformation of the structure shall not exceed the prescribed limits where the structure is subjected to the design seismic forces.

12.1.3 Continuous Load Path and Interconnection A continuous load path, or paths, with adequate strength and stiffness shall be provided to transfer all forces from the point of application to the final point of resistance. All parts of the structure between separation joints shall be interconnected to form a continuous path to the seismic force-resisting system, and the connections shall be capable of transmitting the seismic force, F_p, induced by the parts being connected. Any smaller portion of the structure shall be tied to the remainder of the structure with elements that have a design strength capable of transmitting a seismic force of 0.133 times the short-period design spectral response acceleration parameter, S_{DS}, times the weight of the smaller portion or 5% of the portion's weight, whichever is greater. This connection force does not apply to the overall design of the seismic force-resisting system. Connection design forces need not exceed the maximum forces that the structural system can deliver to the connection.

12.1.4 Connection to Supports A positive connection for resisting a horizontal force acting parallel to the member shall be provided for each beam, girder, or truss, either directly to its supporting elements or to slabs designed to act as diaphragms. Where the connection is through a diaphragm, then the member's supporting element must also be connected to the diaphragm. The connection shall have a minimum design strength of 5% of the dead plus live load reaction.

12.1.5 Foundation Design The foundation shall be designed to resist the forces developed and to accommodate the movements imparted to the structure and foundation by the design ground motions. The dynamic nature of the forces, the expected ground motion, the design basis for strength and energy dissipation capacity of the structure, and the dynamic properties of the soil shall be included in the determination of the foundation design criteria. The design and construction of foundations shall comply with Section 12.13.

When calculating load combinations using the load combinations specified in either Section 2.3 or Section 2.4, the weights of foundations shall be considered dead loads in accordance with Section 3.1.2. The dead loads are permitted to include overlying fill and paving materials.

12.1.6 Material Design and Detailing Requirements Structural elements, including foundation elements, shall conform to the material design and detailing requirements set forth in Chapter 14.

12.2 STRUCTURAL SYSTEM SELECTION

12.2.1 Selection and Limitations Except as noted in Section 12.2.1.1, the basic lateral and vertical seismic force-resisting system shall conform to one of the types indicated in Table 12.2-1 or a combination of systems as permitted in Sections 12.2.2, 12.2.3, and 12.2.4. Each system is subdivided by the types of vertical elements used to resist lateral seismic forces. The structural systems used shall be in accordance with the structural system limitations and the limits on structural height, h_n, contained in Table 12.2-1. The appropriate response modification coefficient, R; overstrength factor, Ω_0; and deflection amplification factor, C_d, indicated in Table 12.2-1 shall be used in determining the base shear, element design forces, and design story drift.

Each selected seismic force-resisting system shall be designed and detailed in accordance with the specific requirements for the

H. STEEL SYSTEMS NOT SPECIFICALLY DETAILED FOR SEISMIC RESISTANCE, EXCLUDING CANTILEVER COLUMN SYSTEMS	14.1	3	3	3	NL	NL	NP	NP	NP

[a] Response modification coefficient, R, for use throughout the standard. Note that R reduces forces to a strength level, not an allowable stress level.
[b] Where the tabulated value of the overstrength factor, Ω_0, is greater than or equal to 2½, Ω_0 is permitted to be reduced by subtracting the value of 1/2 for structures with flexible diaphragms.
[c] Deflection amplification factor, C_d, for use in Sections 12.8.6, 12.8.7, 12.9.1.2, and 12.12.
[d] NL = Not Limited, and NP = Not Permitted. For metric SI units, multiply by 0.348 m/ft and round to the nearest 0.1 m.
[e] See Section 12.2.5.4 for a description of seismic force-resisting systems limited to buildings with a structural height, h_n, of 240 ft (73.2 m) or less.
[f] See Section 12.2.5.4 for seismic force-resisting systems limited to buildings with a structural height, h_n, of 160 ft (48.8 m) or less.
[g] In Section 2.3 of ACI 318. A shear wall is defined as a structural wall.
[h] In Section 2.3 of ACI 318. The definition of "special structural wall" includes precast and cast-in-place construction.
[i] An increase in structural height, h_n, to 45 ft (13.7 m) is permitted for single-story storage warehouse facilities.
[j] Steel ordinary concentrically braced frames are permitted in single-story buildings up to a structural height, h_n, of 60 ft (18.3 m) where the dead load of the roof does not exceed 20 lb/ft^2 (0.96 kN/m^2) and in penthouse structures.
[k] See Section 12.2.5.7 for limitations in structures assigned to Seismic Design Categories D, E, or F.
[l] See Section 12.2.5.6 for limitations in structures assigned to Seismic Design Categories D, E, or F.
[m] In Section 2.3 of ACI 318, the definition of "special moment frame" includes precast and cast-in-place construction.
[n] Cold-formed steel—special bolted moment frames shall be limited to one story in height in accordance with ANSI/AISI S400.
[o] Alternately, the seismic load effect including overstrength, E_{mh}, is permitted to be based on the expected strength determined in accordance with ANSI/AISI S400.
[p] Ordinary moment frame is permitted to be used in lieu of intermediate moment frame for Seismic Design Category B or C.
[q] Structural height, h_n, shall not be less than 60 ft (18.3m).

@seismicisolation

system as set forth in the applicable reference document listed in Table 12.2-1 and the additional requirements set forth in Chapter 14.

Nothing contained in this section shall prohibit the use of alternative procedures for the design of individual structures that demonstrate acceptable performance in accordance with the requirements of Section 1.3.1.3 of this standard.

12.2.1.1 Alternative Structural Systems Use of seismic force-resisting systems not contained in Table 12.2-1 shall be permitted contingent on submittal to and approval by the Authority Having Jurisdiction and independent structural design review of an accompanying set of design criteria and substantiating analytical and test data. The design criteria shall specify any limitations on system use, including Seismic Design Category and height; required procedures for designing the system's components and connections; required detailing; and the values of the response modification coefficient, R; overstrength factor, Ω_0; and deflection amplification factor, C_d. The submitted data shall establish the system's nonlinear dynamic characteristics and demonstrate that the design criteria result in a probability of collapse conditioned on the occurrence of MCE_R shaking not greater than 10% for Risk Category II structures. The conditional probability of collapse shall be determined based on a nonlinear analytical evaluation of the system and shall account for sources of uncertainty in quality of the design criteria, modeling fidelity, laboratory test data, and ground motions. Structural design review shall conform to the criteria of Section 16.5.

12.2.1.2 Elements of Seismic Force-Resisting Systems Elements of seismic force-resisting systems, including members and their connections, shall conform to the detailing requirements specified in Table 12.2-1 for the selected structural system.

EXCEPTION: Substitute elements that do not conform to the requirements specified in Table 12.2-1 shall be permitted contingent on submittal to and approval by the Authority Having Jurisdiction of all of the following:

1. In-depth description of the methodology used to evaluate equivalency of the substitute element for the seismic force-resisting system of interest, or reference to published documentation describing the methodology in depth.
2. Justification of the applicability of the equivalency methodology, including but not limited to consideration of the similarity of the forces transferred across the connection between the substitute and conforming elements and the balance of the seismic force-resisting system, and the similarity between the substitute and conforming element on the distribution of forces and displacements in the balance of the structure.
3. A design procedure for the substitute elements, including procedures to determine design strength stiffness, detailing, connections, and limitations to applicability and use.
4. Requirements for the manufacturing, installation, and maintenance of the substitute elements.
5. Experimental evidence demonstrating that the hysteretic characteristics of the conforming and substitute elements are similar through deformation levels anticipated in response to MCE_R shaking. The evaluation of experimental evidence shall include assessment of the ratio of the measured maximum strength to design strength; the ratio of the measured initial stiffness to design stiffness; the ultimate deformation capacity; and the cyclic strength and stiffness deterioration characteristics of the conforming and substitute elements.
6. Evidence of independent structural design review, in accordance with Section 16.5, or review by a third party acceptable to the Authority Having Jurisdiction, of conformance to the requirements of this section.

12.2.2 Combinations of Framing Systems in Different Directions Different seismic force-resisting systems are permitted to be used to resist seismic forces along each of the two orthogonal axes of the structure. Where different systems are used, the respective R, C_d, and Ω_0 coefficients shall apply to each system, including the structural system limitations contained in Table 12.2-1.

12.2.3 Combinations of Framing Systems in the Same Direction Where different seismic force-resisting systems are used in combination to resist seismic forces in the same direction, other than those combinations considered as dual systems, the design shall comply with the requirements of this section. The most stringent applicable structural system limitations contained in Table 12.2-1 shall apply, except as otherwise permitted by this section.

12.2.3.1 R, C_d, and Ω_0 Values for Vertical Combinations Where a structure has a vertical combination in the same direction, the following requirements shall apply.

1. Where the lower system has a lower response modification coefficient, R, the design coefficients (R, Ω_0, and C_d) for the upper system are permitted to be used to calculate the forces and drifts of the upper system. For the design of the lower system, the design coefficients (R, Ω_0, and C_d) for the lower system shall be used. Forces transferred from the upper system to the lower system shall be increased by multiplying by the ratio of the higher response modification coefficient to the lower response modification coefficient.
2. Where the upper system has a lower response modification coefficient, the design coefficients (R, Ω_0, and C_d) for the upper system shall be used for both systems.

EXCEPTIONS:

1. Rooftop structures not exceeding two stories in height and 10% of the total structure weight.
2. Other supported structural systems with a weight equal to or less than 10% of the weight of the structure.
3. Detached one- and two-family dwellings of light-frame construction.

12.2.3.2 Two-Stage Analysis Procedure for Vertical Combinations of Systems A two-stage equivalent lateral force procedure is permitted to be used for structures that have a flexible upper portion above a rigid lower portion, provided the design of the structure complies with all of the following.

(a) The stiffness of the lower portion shall be at least 10 times the stiffness of the upper portion. For purposes of determining this ratio, the base shear shall be computed and distributed vertically according to Section 12.8. Using these forces, the stiffness for each portion shall be computed as the ratio of the base shear for that portion to the elastic displacement, δ_e, computed at the top of that portion, considering the portion fixed at its base. For the lower portion, the applied forces shall include the reactions from the upper portion, modified as required in Item (d).

@seismicisolation
@seismicisolation

(b) The period of the entire structure shall not be greater than 1.1 times the period of the upper portion considered as a separate structure supported at the transition from the upper to the lower portion.
(c) The upper portion shall be designed as a separate structure using the appropriate values of R and ρ.
(d) The lower portion shall be designed as a separate structure using the appropriate values of R and ρ while meeting the requirements of Section 12.2.3.1. The reactions from the upper portion shall be those determined from the analysis of the upper portion, where the effects of the horizontal seismic load, E_h, are amplified by the ratio of the R/ρ of the upper portion over R/ρ of the lower portion. This ratio shall not be less than 1.0.
(e) The upper portion is analyzed with the equivalent lateral force or modal response spectrum procedure, and the lower portion is analyzed with the equivalent lateral force procedure.
(f) The structural height of the upper portion shall not exceed the height limits of Table 12.2-1 for the seismic force-resisting system used, where the height is measured from the base of the upper portion.
(g) Where Horizontal Irregularity Type 4 or Vertical Irregularity Type 3 exists at the transition from the upper to the lower portion, the reactions from the upper portion shall be amplified in accordance with Sections 12.3.3.4, 12.10.1.1, and 12.10.3.3, in addition to amplification required by Item (d).

12.2.3.3 R, C_d, and Ω_0 Values for Horizontal Combinations The value of the response modification coefficient, R, used for design in the direction under consideration shall not be greater than the least value of R for any of the systems used in that direction. The deflection amplification factor, C_d, and the overstrength factor, Ω_0, shall be consistent with R required in that direction.

EXCEPTION: Resisting elements are permitted to be designed using the least value of R for the different structural systems found in each independent line of resistance if the following three conditions are met: (1) Risk Category I or II building, (2) two stories or fewer above grade plane, and (3) use of light-frame construction or flexible diaphragms. The value of R used for design of diaphragms in such structures shall not be greater than the least value of R for any of the systems used in that same direction.

12.2.3.4 Two-Stage Analysis Procedure for One-Story Structures with Flexible Diaphragms and Rigid Vertical Elements A two-stage equivalent lateral force procedure shall be permitted to be used for determination of seismic design forces in vertical elements of one-story structures having flexible diaphragms supported by rigid vertical elements, provided that the structure conforms to all of the following:

(a) The structure shall comply with the requirements of Section 12.10.4.
(b) The seismic design forces to the vertical elements in each horizontal direction shall be taken as the sum of forces contributed by the effective seismic weight tributary to the diaphragm and forces contributed by the effective seismic weight tributary to the in-plane vertical elements, as follows:
1. Forces contributed by the effective seismic weight tributary to the diaphragm shall be the reactions from diaphragm forces determined in accordance with Section 12.10.4.2.1, amplified by the ratio of R_{diaph} divided by R/ρ of the vertical seismic force-resisting system. This ratio shall not be taken as less than 1.0.
2. Forces contributed by the effective seismic weight tributary to the in-plane rigid vertical elements shall be determined in accordance with Section 12.8 using the period calculated in accordance with Section 12.8.

12.2.4 Combination Framing Detailing Requirements Structural members common to different framing systems used to resist seismic forces in any direction shall be designed using the detailing requirements of Chapter 12 required by the highest response modification coefficient, R, of the connected framing systems.

12.2.5 System-Specific Requirements The structural framing system shall also comply with the following system-specific requirements of this section.

12.2.5.1 Dual System For a dual system, the moment frames shall be capable of resisting at least 25% of the design seismic forces. The total seismic force resistance is to be provided by the combination of the moment frames and the shear walls or braced frames in proportion to their rigidities.

12.2.5.2 Cantilever Column Systems Cantilever column systems are permitted as indicated in Table 12.2-1 and as follows. Where not otherwise limited by the applicable material standard, the required axial strength of individual cantilever column elements, considering only the load combinations that include seismic load effects, shall not exceed 15% of the available axial strength, including slenderness effects.

Foundation and other elements used to provide overturning resistance at the base of cantilever column elements shall be designed to resist the seismic load effects, including overstrength of Section 12.4.3.

12.2.5.3 Inverted Pendulum-Type Structures Regardless of the structural system selected, inverted pendulums as defined in Section 11.2 shall comply with this section. Supporting columns or piers of inverted pendulum-type structures shall be designed for the bending moment calculated at the base determined using the procedures given in Section 12.8 and varying uniformly to a moment at the top equal to one-half the calculated bending moment at the base.

12.2.5.4 Increased Structural Height Limit for Steel Eccentrically Braced Frames, Steel Special Concentrically Braced Frames, Steel Buckling-Restrained Braced Frames, Steel Special Plate Shear Walls, Steel and Concrete Coupled Composite Plate Shear Walls, Reinforced Concrete Ductile Coupled Walls, and Special Reinforced Concrete Shear Walls The limits on structural height, h_n, in Table 12.2-1 are permitted to be increased from 160 ft (50 m) to 240 ft (75 m) for structures assigned to Seismic Design Category D or E and from 100 ft (30 m) to 160 ft (50 m) for structures assigned to Seismic Design Category F, provided that the seismic force-resisting systems are limited to steel eccentrically braced frames, steel special concentrically braced frames, steel buckling-restrained braced frames, steel special plate shear walls, steel and concrete coupled composite plate shear walls, reinforced concrete ductile coupled walls, or special reinforced concrete cast-in-place shear walls and both of the following requirements are met:

1. The structure shall not have a Type 1 horizontal irregularity with a TIR > 1.4, and
2. The steel eccentrically braced frames, steel special concentrically braced frames, steel buckling-restrained braced frames, steel special plate shear walls, steel and concrete coupled composite plate shear walls, reinforced concrete

@seismicisolation

ductile coupled walls, or special reinforced cast-in-place concrete shear walls in any one plane shall resist no more than 60% of the total seismic forces in each direction, neglecting accidental torsional effects.

12.2.5.5 Special Moment Frames in Structures Assigned to Seismic Design Categories D through F For structures assigned to Seismic Design Categorie D, E, or F, where a special moment frame is required by Table 12.2-1 because of the structural system limitations, the frame shall be continuous to the base.

A special moment frame that is used but not required by Table 12.2-1 is permitted to be discontinued above the base and supported by a more rigid system with a lower response modification coefficient, R, provided that the requirements of Sections 12.2.3.1 and 12.3.3.5 are met.

12.2.5.6 Steel Ordinary Moment Frames

12.2.5.6.1 Seismic Design Category D or E

(a) Single-story steel ordinary moment frames in structures assigned to Seismic Design Category D or E are permitted up to a structural height, h_n, of 65 ft (20 m) where the dead load supported by and tributary to the roof does not exceed 20 lb/ft^2 (0.96 kN/m^2). In addition, the dead load of the exterior walls more than 35 ft (10.6 m) above the base tributary to the moment frames shall not exceed 20 lb/ft^2 (0.96 kN/m^2).

EXCEPTION: Single-story structures with steel ordinary moment frames whose purpose is to enclose equipment or machinery and whose occupants are engaged in maintenance or monitoring of that equipment, machinery, or their associated processes shall be permitted to be of unlimited height where the sum of the dead and equipment loads supported by and tributary to the roof does not exceed 20 lb/ft^2 (0.96 kN/m^2). In addition, the dead load of the exterior wall system, including exterior columns more than 35 ft (10.6 m) above the base, shall not exceed 20 lb/ft^2 (0.96 kN/m^2). For determining compliance with the exterior wall or roof load limits, the weight of equipment or machinery, including cranes, not self-supporting for all loads shall be assumed to be fully tributary to the area of the adjacent exterior wall or roof not to exceed 600 ft^2 (55.8 m^2), regardless of its height above the base of the structure.

(b) Steel ordinary moment frames in structures assigned to Seismic Design Category D or E not meeting the limitations set forth in Section 12.2.5.6.1.a are permitted within light-frame construction up to a structural height, h_n, of 35 ft (10.6 m) where neither the roof dead load nor the dead load of any floor above the base supported by and tributary to the moment frames exceeds 35 lb/ft^2 (1.68 kN/m^2). In addition, the dead load of the exterior walls tributary to the moment frames shall not exceed 20 lb/ft^2 (0.96 kN/m^2).

12.2.5.6.2 Seismic Design Category F Single-story steel ordinary moment frames in structures assigned to Seismic Design Category F are permitted up to a structural height, h_n, of 65 ft (20 m) where the dead load supported by and tributary to the roof does not exceed 20 lb/ft^2 (0.96 kN/m^2). In addition, the dead load of the exterior walls tributary to the moment frames shall not exceed 20 lb/ft^2 (0.96 kN/m^2).

12.2.5.7 Steel Intermediate Moment Frames

12.2.5.7.1 Seismic Design Category D

(a) Single-story steel intermediate moment frames in structures assigned to Seismic Design Category D are permitted up to a structural height, h_n, of 65 ft (20 m) where the dead load supported by and tributary to the roof does not exceed 20 lb/ft^2 (0.96 kN/m^2). In addition, the dead load of the exterior walls more than 35 ft (10.6 m) above the base tributary to the moment frames shall not exceed 20 lb/ft^2 (0.96 kN/m^2).

EXCEPTION: Single-story structures with steel intermediate moment frames whose purpose is to enclose equipment or machinery and whose occupants are engaged in maintenance or monitoring of that equipment, machinery, or their associated processes shall be permitted to be of unlimited height where the sum of the dead and equipment loads supported by and tributary to the roof does not exceed 20 lb/ft^2 (0.96 kN/m^2). In addition, the dead load of the exterior wall system, including exterior columns more than 35 ft (10.6 m) above the base, shall not exceed 20 lb/ft^2 (0.96 kN/m^2). For determining compliance with the exterior wall or roof load limits, the weight of equipment or machinery, including cranes, not self-supporting for all loads shall be assumed to be fully tributary to the area of the adjacent exterior wall or roof not to exceed 600 ft^2 (55.8 m^2), regardless of its height above the base of the structure.

(b) Steel intermediate moment frames in structures assigned to Seismic Design Category D not meeting the limitations set forth in Section 12.2.5.7.1.a are permitted up to a structural height, h_n, of 35 ft (10.6 m).

12.2.5.7.2 Seismic Design Category E

(a) Single-story steel intermediate moment frames in structures assigned to Seismic Design Category E are permitted up to a structural height, h_n, of 65 ft (20 m) where the dead load supported by and tributary to the roof does not exceed 20 lb/ft^2 (0.96 kN/m^2). In addition, the dead load of the exterior walls more than 35 ft (10.6 m) above the base tributary to the moment frames shall not exceed 20 lb/ft^2 (0.96 kN/m^2).

EXCEPTION: Single-story structures with steel intermediate moment frames whose purpose is to enclose equipment or machinery and whose occupants are engaged in maintenance or monitoring of that equipment, machinery, or their associated processes shall be permitted to be of unlimited height where the sum of the dead and equipment loads supported by and tributary to the roof does not exceed 20 lb/ft^2 (0.96 kN/m^2). In addition, the dead load of the exterior wall system, including exterior columns more than 35 ft (10.6 m) above the base, shall not exceed 20 lb/ft^2 (0.96 kN/m^2). For determining compliance with the exterior wall or roof load limits, the weight of equipment or machinery, including cranes, not self-supporting for all loads shall be assumed fully tributary to the area of the adjacent exterior wall or roof not to exceed 600 ft^2 (55.8 m^2), regardless of its height above the base of the structure.

(b) Steel intermediate moment frames in structures assigned to Seismic Design Category E not meeting the limitations

@seismicisolation
@seismicisolation

set forth in Section 12.2.5.7.2.a are permitted up to a structural height, h_n, of 35 ft (10.6 m) where neither the roof dead load nor the dead load of any floor above the base supported by and tributary to the moment frames exceeds 35 lb/ft^2 (1.68 kN/m^2). In addition, the dead load of the exterior walls tributary to the moment frames shall not exceed 20 lb/ft^2 (0.96 kN/m^2).

12.2.5.7.3 Seismic Design Category F

(a) Single-story steel intermediate moment frames in structures assigned to Seismic Design Category F are permitted up to a structural height, h_n, of 65 ft (20 m) where the dead load supported by and tributary to the roof does not exceed 20 lb/ft^2 (0.96 kN/m^2). In addition, the dead load of the exterior walls tributary to the moment frames shall not exceed 20 lb/ft^2 (0.96 kN/m^2).

(b) Steel intermediate moment frames in structures assigned to Seismic Design Category F not meeting the limitations set forth in Section 12.2.5.7.3.a are permitted within light-frame construction up to a structural height, h_n, of 35 ft (10.6 m) where neither the roof dead load nor the dead load of any floor above the base supported by and tributary to the moment frames exceeds 35 lb/ft^2 (1.68 kN/m^2). In addition, the dead load of the exterior walls tributary to the moment frames shall not exceed 20 lb/ft^2 (0.96 kN/m^2).

12.2.5.8 Shear Wall–Frame Interactive Systems The shear strength of the shear walls of the shear wall–frame interactive system shall be at least 75% of the design story shear at each story. The frames of the shear wall–frame interactive system shall be capable of resisting at least 25% of the design story shear in every story.

12.3 DIAPHRAGM FLEXIBILITY, CONFIGURATION IRREGULARITIES, AND REDUNDANCY

12.3.1 Diaphragm Flexibility The structural analysis shall consider the relative stiffnesses of diaphragms and the vertical elements of the seismic force-resisting system. Unless a diaphragm can be idealized as either flexible or rigid in accordance with Sections 12.3.1.1, 12.3.1.2, or 12.3.1.3, the structural analysis shall explicitly include consideration of the stiffness of the diaphragm (i.e., semirigid modeling assumption). Diaphragms in hillside structures of light-frame construction shall be modeled in accordance with Section 12.3.1.4.

12.3.1.1 Flexible Diaphragm Condition Diaphragms constructed of untopped steel decking or wood structural panels are permitted to be idealized as flexible if any of the following conditions exist:

1. In structures where the vertical elements are steel braced frames; steel and concrete composite braced frames; or concrete, masonry, steel, or steel and concrete composite shear walls.
2. In one- and two-family dwellings.
3. In structures of light-frame construction where all of the following conditions are met:
   (a) Topping of concrete or similar materials is not placed over wood structural panel diaphragms except for nonstructural topping no greater than 1.5 in. (38 mm) thick, and
   (b) Each line of vertical elements of the seismic force-resisting system complies with the allowable story drift of Table 12.12-1.

12.3.1.2 Rigid Diaphragm Condition Diaphragms of concrete slabs or concrete-filled metal deck with span-to-depth ratios of 3 or less in structures that do not have a Type 2, 3, 4, or 5 Horizontal Structural Irregularity are permitted to be idealized as rigid.

12.3.1.3 Calculated Flexible Diaphragm Condition Diaphragms not satisfying the conditions of Sections 12.3.1.1 or 12.3.1.2 are permitted to be idealized as flexible provided

$$\frac{\delta_{MDD}}{\Delta_{ADVE}} > 2 \qquad (12.3\text{-}1)$$

where δ_{MDD} and Δ_{ADVE} are as shown in Figure 12.3-1. The loading used in this calculation shall be that prescribed in Section 12.8.

12.3.1.4 Diaphragms in Hillside Light-Frame Structures Diaphragms in hillside structures of light-frame construction shall be modeled as rigid or semirigid when they are seismically braced on one or more sides directly by the foundation or foundation stem wall or by a framed wall with a clear height of 2 ft (0.61 m) or less, and are also seismically braced on other sides by framed walls with any wall having a clear height of more than 7 ft (2.13 m). Other diaphragms shall be idealized as flexible or rigid in accordance with Sections 12.3.1.1, 12.3.1.2, or 12.3.1.3, or shall be modeled as semirigid.

12.3.2 Irregular and Regular Classification Structures shall be classified as having a structural irregularity based on the criteria in this section. Such classification shall be based on their structural configurations.

12.3.2.1 Horizontal Irregularity Structures that have one or more of the irregularity types listed in Tables 12.3-1 and 12.3-1a shall be designated as having a horizontal structural irregularity. Such structures assigned to the Seismic Design Categories listed in Table 12.3-1 shall comply with the requirements in the sections referenced in the tables.

12.3.2.1.1 Torsional Irregularity Ratio A Torsional Irregularity Ratio (TIR) shall be calculated for each story and for each accidental torsion case:

$$TIR = \frac{\Delta_{\max}}{\Delta_{\text{avg}}} \qquad (12.3\text{-}2)$$

where $\Delta_{\max}$ is the maximum story drift at the building's edge subjected to lateral forces using the equivalent lateral force procedure per Section 12.8 with the application of accidental torsion per Section 12.8.4 and $A_x = 1.0$; and Δ_{avg} is the average of the story drifts at the two opposing edges of the building

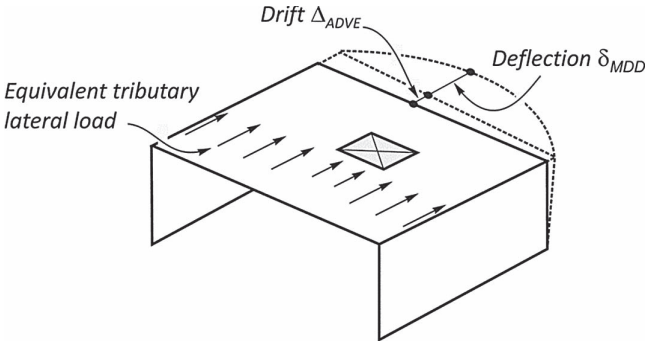

Figure 12.3-1. Flexible diaphragm.

@seismicisolation

Table 12.3-1. Horizontal Structural Irregularities.

Type	Description	Reference Section*	Seismic Design Category Application
1	**Torsional Irregularity:** Torsional irregularity, defined to exist where either: • More than 75% of any story's lateral strength below the diaphragm is provided at or on one side of the center of mass, or • The Torsional Irregularity Ratio (TIR) exceeds 1.2. The story lateral strength is the total strength of all seismic-resisting elements sharing the story shear for the direction under consideration.	Table 12.3-1a, 12.3.3.5, 12.5.1.2 12.7.3 12.8.4.3 12.8.6 16.3.4	B, C, D, E, F C, D, E, F B, C, D, E, F C, D, E, F C, D, E, F B, C, D, E, F
2.	**Reentrant Corner Irregularity:** Reentrant corner irregularity, defined to exist where both plan projections of the structure beyond a reentrant corner are greater than 20% of the plan dimension of the structure in the given direction.	12.3.3.5	D, E, F
3.	**Diaphragm Discontinuity Irregularity:** Diaphragm discontinuity irregularity, defined to exist where there is a diaphragm with an abrupt discontinuity or variation in stiffness, including one that has a cutout or open area greater than 25% of the gross enclosed diaphragm area, or a change in effective diaphragm stiffness of more than 50% from one story to the next.	12.3.3.5	D, E, F
4.	**Out-of-Plane Offset Irregularity:** Out-of-plane offset irregularity, defined to exist where there is a discontinuity in a lateral force-resistance path, such as an out-of-plane offset of at least one of the vertical elements.	12.3.3.5 12.3.3.5 12.7.3 16.3.4	B, C, D, E, F D, E, F B, C, D, E, F B, C, D, E, F
5.	**Nonparallel System Irregularity:** Nonparallel system irregularity, defined to exist where vertical lateral force-resisting elements are not parallel to the major orthogonal axes of the seismic force-resisting system.	12.5.3 12.5.4 12.7.3 16.3.4	C, D, E, F B, C, D, E, F B, C, D, E, F

*See Section 12.8.1.3 for requirement for any structure with an irregularity listed in this table.

Table 12.3-1a. Reference Sections for Type 1 Horizontal Torsional Irregularity (TIR).

Horizontal Torsional Irregularity (TIR)	Seismic Design Category	Reference Section	Description[a]
>1.2[b]	B, C, D, E, F	15.4.1	Inclusion of accidental torsion in nonbuilding structures not similar to buildings
		16.3.4	Mass offset in Nonlinear Response History analysis
		17.2.2	Irregularities in Seismically Isolated Buildings
		18.2.3.2	Applicability of Equivalent Lateral Force Procedure for structures with damping systems
	C, D, E, F	12.7.3	Use of 3D analytical model
	D, E, F	12.5.4	Use of orthogonal load combinations
		12.8.4.2 and 12.8.4.3	Inclusion of amplified accidental torsion
		12.8.6	Story drift for purpose of comparing to drift limits, computing P-Delta, and checking deformation compatibility must be computed at the edge with the largest drift.
	D, E, F	12.3.3.4	Amplification of design force for collectors, their connections, and connections of diaphragms to collectors or vertical elements of the seismic force-resisting system (SFRS)
>1.4	B, C, D, E, F	18.2.1.1	Minimum seismic base shear for structures with damping systems
	D, E, F	12.2.5.4	Increased structural height limits not allowed for certain systems
	D, E, F	12.5.4	Use of orthogonal load combinations
		12.8.4.2	Include accidental torsion
>1.4 in both directions	D, E, F	12.3.4.2.1	Criteria for setting redundancy factor = 1.3
>1.6	D, E, F	12.9.1.5	Restrictions on use mass offset for accidental torsion in Modal Response Spectrum analysis

[a]Refer to the reference section for the precise requirement.
[b]The requirements for TIR > 1.2 also apply if TIR ≤ 1.2 and if more than 75% of the story's lateral strength below the diaphragm is provided at or on one side of the center of mass per Table 12.3-1.
Notes: The requirements in this table are cumulative; thus for TIR > 1.4 or 1.6, all the requirements for TIR > 1.2 also apply.

@seismicisolation
@seismicisolation

Table 12.3-2. Vertical Structural Irregularities.

Type	Description	Reference Section*	Seismic Design Category Application
1a.	**Stiffness–Soft Story Irregularity** is defined to exist where there is a story in which the lateral stiffness is less than 70% of that in the story above or, where there are at least three stories above, less than 80% of the average stiffness of the three stories above.	-	-
1b.	**Stiffness–Extreme Soft Story Irregularity** is defined to exist where there is a story in which the lateral stiffness is less than 60% of that in the story above or, where there are at least three stories above, less than 70% of the average stiffness of the three stories above.	12.3.3.1	E, F
2.	**Vertical Geometric Irregularity** is defined to exist where the horizontal dimension of the seismic force-resisting system in any story is more than 130% of that in an adjacent story.	-	-
3.	**In-Plane Discontinuity in Vertical Lateral Force-Resisting Element Irregularity** is defined to exist where there is an in-plane offset of a vertical seismic force-resisting element resulting in overturning demands on supporting structural elements.	12.3.3.4 12.3.3.5	B, C, D, E, F D, E, F
4a.	**Discontinuity in Lateral Strength–Weak Story Irregularity** is defined to exist where the story lateral strength is less than that in the story above. The story lateral strength is the total lateral strength of all seismic force-resisting system elements resisting the story shear for the direction under consideration.	12.3.3.1	E, F
4b.	**Discontinuity in Lateral Strength–Extreme Weak Story Irregularity** is defined to exist where the story lateral strength is less than 65% of that in the story above. The story lateral strength is the total lateral strength of all seismic force-resisting system elements resisting the story shear for the direction under consideration.	12.3.3.1 12.3.3.2 12.3.3.3	E, F D B, C

*See Section 12.8.1.3 for requirement for any structure with an irregularity listed in this table.

determined using the same loading and diaphragm rigidity as applied for the determination of Δ_{max}.

For the purpose of computing Δ_{max} and Δ_{avg}, it shall be permitted to assume the diaphragm is rigid for structures with rigid or semirigid diaphragms. The TIR for the building is the maximum value from the values computed for each story and each direction. The TIR shall not apply to structures with flexible diaphragms.

12.3.2.2 Vertical Irregularity Structures that have one or more of the irregularity types listed in Table 12.3-2 shall be designated as having a vertical structural irregularity. Such structures assigned to the Seismic Design Categories listed in Table 12.3-2 shall comply with the requirements in the sections referenced in that table.

EXCEPTIONS:

1. Vertical structural irregularities of Types 1a and 1b in Table 12.3-2 do not apply where no design story drift ratio is greater than 130% of the story drift ratio of the next story above. For this exception the following need not be considered:
   (a) Torsional effects, and
   (b) The design story-drift ratio relationship of the top two stories of the structure.
2. Vertical structural irregularities of Types 1a and 1b in Table 12.3-2 are not required to be considered for one-story buildings in any Seismic Design Category or for two-story buildings assigned to Seismic Design Category B, C, or D.

12.3.3 Limitations and Additional Requirements for Systems with Structural Irregularities

12.3.3.1 Prohibited Vertical Irregularities for Seismic Design Category E or F Structures assigned to Seismic Design Category E or F that have vertical irregularities Type 1b, 4a, or 4b of Table 12.3-2 shall not be permitted.

EXCEPTION: Structures assigned to Seismic Design Category E or F that have vertical irregularity Type 4a shall be permitted where the story lateral strength is not less than 80% of that in the story above.

12.3.3.2 Prohibited Vertical Irregularities for Seismic Design Category D Structures assigned to Seismic Design Category D that have vertical irregularity Type 4b of Table 12.3-2 shall not be permitted.

12.3.3.3 Extreme Weak Stories for Seismic Design Categories B or C Structures assigned to Seismic Design Category B or C that have a vertical irregularity Type 4b, as defined in Table 12.3-2, shall not be more than two stories or 30 ft (9 m) in structural height, h_n.

EXCEPTION: The limit does not apply where the "weak" story is capable of resisting a total seismic force equal to Ω_0 times the design force prescribed in Section 12.8.

12.3.3.4 Elements Supporting Discontinuous Walls or Frames Structural elements supporting discontinuous walls or frames of structures that have horizontal irregularity Type 4 of Table 12.3-1 or vertical irregularity Type 3 of Table 12.3-2 shall be designed to resist the seismic load effects, including overstrength of Section 12.4.3. The connections of such discontinuous walls or frames to the supporting members shall be adequate to transmit the forces for which the discontinuous walls or frames were required to be designed.

12.3.3.5 Increase in Forces Caused by Irregularities for Seismic Design Categories D through F For structures assigned to Seismic Design Category D, E, or F and having a horizontal structural irregularity of Type 1, 2, 3, or 4 in Table 12.3-1 or a vertical structural irregularity of Type 3 in Table 12.3-2, the design forces determined from Section 12.10.1.1 shall be increased 25% at each diaphragm level where the irregularity occurs for the following elements of the seismic force-resisting system:

@seismicisolation

1. Connections of diaphragms to vertical elements and to collectors, and
2. Collectors and their connections, including connections to vertical elements of the seismic force-resisting system.

EXCEPTION: Forces calculated using the seismic load effects including overstrength of Section 12.4.3 need not be increased.

12.3.4 Redundancy A redundancy factor, ρ, shall be assigned to the seismic force-resisting system in each of two orthogonal directions for all structures in accordance with this section.

12.3.4.1 Conditions Where Value of ρ is 1.0 The value of ρ is permitted to equal 1.0 for the following:

1. Structures assigned to Seismic Design Category B or C;
2. Drift calculation and P-delta effects;
3. Design of nonstructural components;
4. Design of nonbuilding structures that are not similar to buildings;
5. Design of collector elements, splices, and their connections for which the seismic load effects including overstrength of Section 12.4.3 are used;
6. Design of members or connections where the seismic load effects, including overstrength of Section 12.4.3, are required for design;
7. Diaphragm seismic design forces determined using Equation (12.10-1), including the limits imposed by Equations (12.10-2) and (12.10-3);
8. Diaphragm seismic design forces determined in accordance with Section 12.10.4;
9. Structures with damping systems designed in accordance with Chapter 18; and
10. Design of structural walls for out-of-plane forces, including their anchorage.

12.3.4.2 Redundancy Factor, ρ, for Seismic Design Categories D through F For structures assigned to Seismic Design Categorie D, E, or F in the direction of interest, ρ shall be taken as 1.3 unless one of the following two conditions is met, whereby ρ is permitted to be taken as 1.0.

1. For each story where the story shear is greater than 35% of the base shear in the direction of interest, the following conditions shall be met with the notional removal of any lateral force resisting element or connection as indicated in Table 12.3-3. Structures that consist of a lateral force-resisting system (LFRS) with elements not listed in Table 12.3-3 need not consider the requirements of this provision.
   (a) There are at least two bays of seismic force-resisting framing on each side of the center of mass.
   (b) The reduction in lateral strength of the story in the direction of interest does not exceed 35%.
   (c) The resulting system with consideration of removal of the element does not have a Type 1 Horizontal Irregularity with a TIR > 1.4.
2. The structure does not have any horizontal irregularities as defined in Section 12.3.2.1 in the direction of interest at all levels, and the seismic force-resisting systems shall consist of at least two bays of seismic force-resisting perimeter framing on each side of the structure at each story resisting more than 35% of the base shear. The number of bays of shear walls shall be as defined in Table 12.3-3.

12.3.4.2.1 Redundancy Factor, ρ, for Structures with Type 1 Horizontal (Torsional) Irregularity with TIR>1.4 in Seismic Design Categories D through F For a structure assigned to Seismic Design Category D, E, or F, and having a Type 1 Horizontal irregularity with TIR > 1.4 in both orthogonal directions at any given level as defined in Table 12.3-1, ρ shall equal 1.3 for the entire structure in both orthogonal directions. For all other structures, including structures with a Type 1 irregularity, the requirements of 12.3.4.2 shall apply.

12.4 SEISMIC LOAD EFFECTS AND COMBINATIONS

12.4.1 Applicability All members of the structure, including those not part of the seismic force-resisting system, shall be designed using the seismic load effects of Section 12.4 unless otherwise exempted by this standard. Seismic load effects are the axial, shear, and flexural member forces resulting from application of horizontal and vertical seismic forces as set forth in Section 12.4.2. Where required, seismic load effects shall include overstrength, as set forth in Section 12.4.3.

12.4.2 Seismic Load Effect The seismic load effect, E, includes effects of both horizontal and vertical ground motions as shown in Eq. (12.4-1) and Eq. (12.4-2).

$$E = E_h + E_v \quad (12.4\text{-}1)$$

$$E = E_h - E_v \quad (12.4\text{-}2)$$

where E_h is the effect of horizontal seismic forces as defined in Section 12.4.2.1, and E_v is the vertical seismic effect applied in the vertical downward direction as determined in Section 12.4.2.2. E_v shall be subject to reversal to the upward direction in accordance with the applicable load combinations.

E_h, and E_v shall be used in load combinations 6 and 7 in Section 2.3.6 and in load combinations 8, 9, and 10 in Section 2.4.5.

12.4.2.1 Horizontal Seismic Load Effect The horizontal seismic load effect, E_h, shall be determined in accordance with Equation (12.4-3) as follows:

Table 12.3-3. Requirements for Each Story Resisting More than 35% of the Base Shear.

Lateral Force-Resisting Element	Condition
Braced frames, Light-frame walls with flat strap bracing	Removal of an individual brace, or connection thereto
Moment frames	Loss of moment resistance at the beam-to-column connections at both ends of a single beam
Shear walls or wall piers with a height-to-length ratio greater than 1.0	Removal of a shear wall bay, or wall pier, with a height-to-length ratio greater than 1.0, or connections thereto. The shear wall and wall pier height-to-length ratios are determined as shown in Figure 12.3-2. A shear wall bay is defined as the length of the wall divided by the story height (rounded down).
Cantilever columns	Loss of moment resistance at the base of any single cantilever column

@seismicisolation

$$E_h = \rho Q_E \quad (12.4\text{-}3)$$

where Q_E is the effects of horizontal seismic forces from V or F_p (where required by Section 12.5.3 or 12.5.4, such effects shall result from application of horizontal forces simultaneously in two directions at right angles to each other), and ρ is the redundancy factor, as defined in Section 12.3.4.

12.4.2.2 Vertical Seismic Load Effect The vertical seismic load effect, E_v, shall be determined in accordance with Equation (12.4-4a) as follows:

$$E_v = 0.2 S_{DS} D \quad (12.4\text{-}4a)$$

where S_{DS} is the design spectral response acceleration parameter at short periods obtained from Section 11.4.5, and D is the effect of dead load.

EXCEPTIONS:

1. Where the option to incorporate the effects of vertical seismic ground motions using the provisions of Section 11.9 is required elsewhere in this standard, the vertical seismic load effect, E_v, shall be determined in accordance with Equation (12.4-4b) as follows:

$$E_v = 0.3 S_{av} D \quad (12.4\text{-}4b)$$

   where S_{av} is the design vertical response spectral acceleration obtained from Section 11.9.3, and D is the effect of dead load.
2. The vertical seismic load effect, E_v, is permitted to be taken as zero for either of the following conditions:
   (a) In Equations (12.4-1), (12.4-2), (12.4-5), and (12.4-6) for structures assigned to Seismic Design Category B, and
   (b) In Equation (12.4-2) where determining demands on the soil–structure interface of foundations.

12.4.3 Seismic Load Effects Including Overstrength The seismic load effect including overstrength, E_m, includes effects of both horizontal and vertical ground motions as shown in Eq. (12.4-5) and Eq. (12.4-6). Where required, the seismic load effects including overstrength shall be determined in accordance with the following:

$$E_m = E_{mh} + E_v \quad (12.4\text{-}5)$$

$$E_m = E_{mh} - E_v \quad (12.4\text{-}6)$$

where

E_m = Seismic load effect including overstrength;
E_{mh} = Effect of horizontal seismic forces, including overstrength as defined in Section 12.4.3.1 or Section 12.4.3.2; and
E_v = Vertical seismic load effect as defined in Section 12.4.2.2. E_v is an applied load in the vertical downward direction. E_v shall be subject to reversal to the upward direction as per the associated load combinations.

E_{mh} and E_v shall be used in load combinations 6 and 7 in Section 2.3.6 and in load combinations 8, 9, and 10 in Section 2.4.5.

12.4.3.1 Horizontal Seismic Load Effect Including Overstrength The effect of horizontal seismic forces including overstrength, E_{mh}, shall be determined in accordance with Equation (12.4-7) as follows:

$$E_{mh} = \Omega_0 Q_E \quad (12.4\text{-}7)$$

where Q_E is the effects of horizontal seismic forces from V, F_{px}, or F_p as specified in Sections 12.8.1, 12.10, or 13.3.1 (where required by Section 12.5.3 or 12.5.4, such effects shall result from application of horizontal forces simultaneously in two directions at right angles to each other); and Ω_0 is the overstrength factor.

E_{mh} need not be taken as larger than E_{cl}, where E_{cl} is the capacity-limited horizontal seismic load effect as defined in Section 11.3.

12.4.3.2 Capacity-Limited Horizontal Seismic Load Effect Where capacity-limited design is required by the material reference document, the seismic load effect, including overstrength, shall be calculated with the capacity-limited horizontal seismic load effect, E_{cl}, substituted for E_{mh} in the load combinations of Section 2.3.6 and Section 2.4.5.

12.4.4 Minimum Upward Force for Horizontal Cantilevers for Seismic Design Categories D through F For a structure assigned to Seismic Design Category D, E, or F, horizontal cantilever structural members shall be designed for a supplemental basic load combination consisting of a minimum net upward force of 0.2 times the dead load for strength design, or 0.14 times the dead load for allowable stress design.

12.5 DIRECTION OF LOADING

12.5.1 Direction of Loading Criteria The directions of application of seismic forces used in the design shall be those that produce the most critical load effects. In lieu of an analysis that finds the critical direction of loading for each element of the seismic force resisting system it is permitted to satisfy this requirement using one of the two methods defined in 12.5.1.1 and 12.5.1.2 subject to the conditions specified in Section 12.5.2, 12.5.3, or 12.5.4.

12.5.1.1 Independent Directional Procedure The design seismic forces shall be applied independently in each of the two orthogonal directions.

12.5.1.2 Orthogonal Directional Combination Procedure The design seismic forces shall be applied in two orthogonal directions simultaneously using one of the two following approaches. Seismic force resisting system member and foundation strength and drift requirements shall be satisfied for all combinations.

(a) For a structure analyzed using the equivalent lateral force analysis procedure of Section 12.8 or the modal response spectrum analysis procedure of Section 12.9.1, the effects of 100% of the seismic forces for one direction shall be combined with the effects of 30% of the forces for the perpendicular direction. Combinations of force effects shall be computed such that each axis has the 100% factor in positive and negative directions.
(b) For a structure analyzed using the linear response history procedure of Section 12.9.2 or the nonlinear response history procedure of Chapter 16, orthogonal pairs of ground motion acceleration histories shall be applied simultaneously.

12.5.2 Seismic Design Category B For a structure assigned to Seismic Design Category B, any method in Section 12.5.1 shall be permitted.

@seismicisolation
@seismicisolation

12.5.3 Seismic Design Category C For a structure assigned to Seismic Design Category C, any method in Section 12.5.1 shall be permitted, unless the structure has a Type 5 horizontal irregularity, in which case the Independent Directional Procedure shall not be permitted.

12.5.4 Seismic Design Categories D through F For a structure assigned to Seismic Design Category D, E, or F, the Independent Directional Procedure method of Section 12.5.1.1 shall be permitted unless one or more of the conditions exist.

(a) The structure has a Type 1 horizontal irregularity.
(b) The structure has a Type 5 horizontal irregularity.
(c) A column that forms part of two or more intersecting seismic force-resisting systems and is subjected to axial load due to seismic forces acting along either principal plan axis exceeding 20% of the axial design strength of the column.
(d) A concrete shear wall that has connected intersecting wall planes and an axial demand exceeding 20% of the axial design strength at any location in the wall due to seismic forces acting along either principal plan axis.
(e) A masonry shear wall that has connected intersecting wall planes and an axial demand exceeding 20% of the axial design strength at any location in the wall due to seismic forces acting along either principal plan axis.
(f) A wood or cold-formed steel light-frame shear wall system that has connected intersecting wall planes and an axial load exceeding 20% of the axial design strength of that wall element at any location within the wall due to seismic forces acting along either principal plan axis.
(g) Cantilever column systems.

EXCEPTION:
Where Items (a) and (b) do not apply, the Independent Directional Procedure is permitted to be used for components of the seismic force-resisting system not listed in Items (c) through (g).

Foundation elements and connections that support elements of structures with any of the preceding conditions (c) through (g) shall be designed using the Orthogonal Direction Combination Procedure of Section 12.5.1.2. In addition, foundations and connections supporting lateral force-resisting system (LFRS) elements that are not coplanar shall be designed using the Orthogonal Direction Combination Procedure.

12.6 ANALYSIS PROCEDURE SELECTION

The structural analysis required by Chapter 12 shall be completed in accordance with the requirements of (a) Equivalent Lateral Force Procedure of Section 12. 8, (b) Modal Response Spectrum Analysis of Section 12.9.1, (c) Linear Response History Analysis of Section 12.9.2, or (d) an analysis procedure approved by the Authority Having Jurisdiction. Nonlinear Response History Analysis of Chapter 16 is allowed for any structure.

12.7 MODELING CRITERIA

12.7.1 Foundation Modeling For purposes of determining seismic loads, it is permitted to consider the structure to be fixed at the base. Alternatively, where foundation flexibility is considered, it shall be in accordance with Section 12.13.3 or Chapter 19.

12.7.2 Effective Seismic Weight The effective seismic weight, W, of a structure shall include the dead load above the base and other loads above the base as follows:

1. In areas used for storage, a minimum of 25% of the floor live load shall be included.
2. Where provision for partitions is made or where required by Section 4.3.2 in the floor load design, the actual partition weight or a minimum weight of 10 lb/ft^2 (0.48 kN/m^2) of floor area, whichever is greater.
3. Total operating weight of permanent equipment.
4. Where the flat roof snow load, P_f, exceeds 45 lb/ft^2 (2.16 kN/m^2), 15% of the uniform design snow load, regardless of actual roof slope.
5. Weight of landscaping and other materials at roof gardens and similar areas, as defined in Section 3.1.4.
6. Weight of fluids and bulk material expected to be present during normal use.

EXCEPTIONS:

(a) Where the total weight of Items 1, 3, 5, and 6 adds no more than 5% to the effective seismic weight at that level, the weight of these items need not be included.
(b) Floor live load in public garages and open parking structures need not be included.
(c) The weights of fluids included as effective seismic weight are permitted to be reduced as justified by a rational fluid-structure interaction analysis.

12.7.3 Structural Modeling A mathematical model of the structure shall be constructed for the purpose of determining member forces and structure displacements resulting from applied loads and any imposed displacements or P-delta effects. The model shall include the stiffness and strength of elements that are significant to the distribution of forces and deformations in the structure and represent the spatial distribution of mass and stiffness throughout the structure.

In addition, the model shall comply with the following:

1. Stiffness properties of concrete and masonry elements shall consider the effects of cracked sections.
2. For steel moment frame systems, the contribution of panel zone deformations to displacement and drift shall be included.

Structures that have horizontal structural irregularity Type 1, 4, or 5 of Table 12.3-1 shall be analyzed using a 3D representation. Where a 3D model is used, a minimum of three degrees of freedom consisting of translation in two orthogonal plan directions and rotation about the vertical axis shall be included at each level of the structure. Where the diaphragms have not been classified as rigid or flexible in accordance with Section 12.3.1, the model shall include representation of the diaphragm's stiffness characteristics and, when dynamic analysis is performed, sufficient degrees of freedom as are required to account for the participation of the diaphragm in the structure's dynamic response. When modal response spectrum or response history analysis is performed, a minimum of three dynamic degrees of freedom consisting of translation in two orthogonal plan directions and torsional rotation about the vertical axis at each level of the structure shall be used.

EXCEPTION: Analysis using a 3D representation is not required for structures with flexible diaphragms that have Type 4 horizontal structural irregularities.

12.7.4 Interaction Effects Moment-resisting frames that are enclosed or adjoined by elements that are more rigid and not considered to be part of the seismic force-resisting system shall be designed so that the action or failure of those elements will not impair the vertical load and seismic force-resisting

@seismicisolation

capability of the frame. The design shall provide for the effect of these rigid elements on the structural system at structural deformations corresponding to the design story drift (Δ) as determined in Section 12.8.6. In addition, the effects of these elements shall be considered where determining whether a structure has one or more of the irregularities defined in Section 12.3.2.

12.8 EQUIVALENT LATERAL FORCE (ELF) PROCEDURE

12.8.1 Seismic Base Shear The seismic base shear, V, in a given direction shall be determined in accordance with the following equation:

$$V = C_s W \tag{12.8-1}$$

where

C_s = The seismic response coefficient determined in accordance with Section 12.8.1.1, and
W = The effective seismic weight per Section 12.7.2.

12.8.1.1 Calculation of Seismic Response Coefficient Where the design spectral acceleration parameter S_a determined in accordance with either Section 11.4.5.1 or Chapter 21 is available, either Method 1 or Method 2 is permitted to determine the seismic response coefficient, C_s. Where Exception 2 of Section 11.4.5 applies, Method 1 shall not be used. The lower bound for the seismic response coefficient, C_s, provided in Item 3 shall be applicable for both Method 1 and Method 2.

Method 1: The seismic response coefficient, C_s, shall be determined in accordance with Equation (12.8-2).

$$C_s = \frac{S_a}{\left(\frac{R}{I_e}\right)} \tag{12.8-2}$$

where

S_a = Design spectral response acceleration parameter defined in Section 11.4.5.1 and determined for the period T defined in Section 12.8.2;
R = Response modification factor in Table 12.2-1; and
I_e = Importance Factor determined in accordance with Section 11.5.1.

Where Equation (12.8-2) is used and the period T is less than the period at which S_a is maximum, the maximum value of S_a shall be used.

Method 2: The seismic response coefficient, C_s, shall be determined in accordance with the following:

$$C_s = \frac{S_{DS}}{\left(\frac{R}{I_e}\right)} \tag{12.8-3}$$

where

S_{DS} = Design spectral response acceleration parameter in the short period range as determined from Section 11.4.5 or 11.4.8;
R = Response modification factor in Table 12.2-1; and
I_e = Importance Factor determined in accordance with Section 11.5.1.

The value of C_s computed in accordance with Equation (12.8-3) need not exceed the following:

for $T \le T_L$,

$$C_s = \frac{S_{D1}}{T\left(\frac{R}{I_e}\right)} \tag{12.8-4}$$

and for $T > T_L$,

$$C_s = \frac{S_{D1} T_L}{T^2\left(\frac{R}{I_e}\right)} \tag{12.8-5}$$

where I_e and R are as defined in this section;

S_{D1} = Design spectral response acceleration parameter at a period of 1.0 s, as determined from Section 11.4.5 or 11.4.6;
T = Fundamental period of the structure(s) determined in Section 12.8.2; and
T_L = Long-period transition period(s) determined in Section 11.4.6.

Lower Bounds for C_s for Both Methods: C_s shall not be less than

$$C_s = 0.044 S_{DS} I_e \ge 0.01 \tag{12.8-6}$$

In addition, for structures located where S_1 is equal to or greater than 0.6, C_s shall not be less than

$$C_s = 0.5 S_1 / (R/I_e) \tag{12.8-7}$$

where S_1 is the mapped maximum considered earthquake spectral response acceleration parameter determined in accordance with Section 11.4.2 or 11.4.4.

12.8.1.2 Soil–Structure Interaction Reduction A soil–structure interaction reduction is permitted where determined using Chapter 19 or other generally accepted procedures approved by the Authority Having Jurisdiction.

12.8.1.3 Maximum S_{DS} Value in Determination of C_s and E_v The values of C_s and E_v are permitted to be calculated using a value of S_{DS} equal to 1.0, but not less than 70% of the value of S_{DS}, as defined in Section 11.4.5, provided that all of the following criteria are met:

1. The structure does not have irregularities, as defined in Section 12.3.2;
2. The structure does not exceed five stories above the lower of the base or grade plane as defined in Section 11.2. Where present, each mezzanine level shall be considered a story for the purposes of this limit;
3. The structure has a fundamental period, T, that does not exceed 0.5 s, as determined using Section 12.8.2;
4. The structure meets the requirements necessary for the redundancy factor, ρ, to be permitted to be taken as 1.0, in accordance with Section 12.3.4.2;
5. The site soil properties are not classified as Site Class E or F, as defined in Section 11.4.3;
6. The structure is classified as Risk Category I or II, as defined in Section 1.5.1; and
7. The response modification coefficient, R, as defined in Table 12.2-1, is 3 or greater.

12.8.2 Period Determination The fundamental period of the structure, T, in the direction under consideration shall be established using the structural properties and deformational characteristics of the resisting elements in a properly

@seismicisolation

Table 12.8-1. Coefficient for Upper Limit on Calculated Period.

Design Spectral Response Acceleration Parameter at 1 s, S_{D1}	Coefficient C_u
≥ 0.4	1.4
0.3	1.4
0.2	1.5
0.15	1.6
≤ 0.1	1.7

substantiated analysis. The fundamental period, T, shall not exceed the product of the coefficient for upper limit on calculated period, C_u, from Table 12.8-1 and the approximate fundamental period, T_a, determined in accordance with Section 12.8.2.1. As an alternative to performing an analysis to determine the fundamental period, T, it is permitted to use the approximate building period, T_a, calculated in accordance with Section 12.8.2.1, directly.

12.8.2.1 Approximate Fundamental Period The approximate fundamental period (T_a), in seconds, shall be determined from the following equation:

$$T_a = C_t h_n^x \tag{12.8-8}$$

where h_n is the structural height as defined in Section 11.2, and the coefficients C_t and x are determined from Table 12.8-2.

Alternatively, it is permitted to determine the approximate fundamental period, T_a, in seconds, from the following equation for structures not exceeding 12 stories above the base as defined in Section 11.2 where the seismic force-resisting system consists entirely of concrete or steel moment-resisting frames and the average story height is at least 10 ft (3 m):

$$T_a = 0.1\,N \tag{12.8-9}$$

where N is the number of stories above the base.

The approximate fundamental period, T_a, in seconds, for masonry or concrete shear wall structures not exceeding 120 ft (36.6 m) in height is permitted to be determined from Equation (12.8-10) as follows:

$$T_a = \frac{C_q}{\sqrt{C_w}} h_n \tag{12.8-10}$$

where
C_q = 0.0019 ft (0.00058 m), and
C_w is calculated from Equation (12.8-11) as follows:

$$C_w = \frac{100}{A_B} \sum_{x}^{i=1} \frac{A_i}{\left[1 + 0.83\left(\frac{h_n}{D_i}\right)^2\right]} \tag{12.8-11}$$

where

A_B = Area of base of structure [ft^2 (m^2)];
A_i = Web area of shear wall i [ft^2 (m^2)];
D_i = Length of shear wall i [ft (m)]; and
x = Number of shear walls in the building effective in resisting lateral forces in the direction under consideration.

12.8.3 Vertical Distribution of Seismic Forces The lateral seismic force, F_x (kip or kN), induced at any level shall be determined from the following equations:

$$F_x = C_{vx} V \tag{12.8-12}$$

$$C_{vx} = \frac{w_x h_x^k}{\sum_n^{i=1} w_i h_i^k} \tag{12.8-13}$$

where

C_{vx} = Vertical distribution factor;
V = Total design lateral force or shear at the base of the structure [kip (kN)];
w_i, w_x = Portion of the total effective seismic weight of the structure (W) located or assigned to level i or x;
h_i, h_x = Height [ft (m)] from the base to level i or x; and
k = Exponent related to the structure period as follows:

For structures that have a period of 0.5 s or less, k = 1;
for structures that have a period of 2.5 s or more, k = 2; and
for structures that have a period between 0.5 and 2.5 s, k shall be 2 or shall be determined by linear interpolation between 1 and 2.

12.8.4 Horizontal Distribution of Forces The seismic design story shear in any story, V_x [kip (kN)], shall be determined from the following equation:

$$V_x = \sum_{i=x}^{n} F_i \tag{12.8-14}$$

where F_i is the portion of the seismic base shear, V [kip (kN)], induced at level i.

Table 12.8-2. Values of Approximate Period Parameters C_t and x.

Structure Type	C_t	x
Moment-resisting frame systems in which the frames resist 100% of the required seismic force and are not enclosed or adjoined by components that are more rigid and will prevent the frames from deflecting where subjected to seismic forces:		
Steel moment-resisting frames	0.028 (0.0724)*	0.8
Concrete moment-resisting frames	0.016 (0.0466)*	0.9
Steel eccentrically braced frames in accordance with Table 12.2-1, line B1 or D1	0.03 (0.0731)*	0.75
Steel buckling-restrained braced frames	0.03 (0.0731)*	0.75
All other structural systems	0.02 (0.0488)*	0.75

*SI equivalents in parentheses.

@seismicisolation

The seismic design story shear, V_x [kip (kN)], shall be distributed to the various vertical elements of the seismic force-resisting system in the story under consideration based on the relative lateral stiffness of the vertical resisting elements and the diaphragm.

12.8.4.1 Inherent Torsion For diaphragms that are not flexible, the distribution of lateral forces at each level shall consider the effect of the inherent torsional moment, M_t, resulting from eccentricity between the locations of the center of mass and the center of rigidity. For flexible diaphragms, the distribution of forces to the vertical elements shall account for the position and distribution of the masses supported.

12.8.4.2 Accidental Torsion

12.8.4.2.1 Accidental Torsion Irregularities Where diaphragms are not flexible, accidental torsion shall be applied to all structures for determination if a horizontal irregularity exists. Accidental torsion shall be included in the analysis and design of structures with the following irregularities as specified in Table 12.3-1:

1. A structure assigned to Seismic Design Category B with Type 1 horizontal structural irregularity and TIR > 1.4.
2. A structure assigned to Seismic Design Category C, D, E, or F with Type 1 horizontal structural irregularity.

12.8.4.2.2 Accidental Torsion Applications Where the consideration of accidental torsion is required, it shall be applied as follows.

1. Accidental torsional moments, M_{ta}, shall be combined with the inherent torsional moment, M_t, resulting from differences in the locations of the center of mass and the center of rigidity.
2. Accidental torsional moments, M_{ta}, shall be determined using an assumed displacement of the center of mass each way from its actual location by a distance equal to 5% of the dimension of the structure perpendicular to the direction of the applied forces.
3. Where earthquake forces are applied concurrently in two orthogonal directions, the required 5% displacement of the center of mass need not be applied in both of the orthogonal directions simultaneously but shall be applied in the direction that produces the greater effect for each element considered.

12.8.4.3 Amplification of Accidental Torsional Moment A structure assigned to Seismic Design Category C, D, E, or F, where Type 1 horizontal structural irregularity exists as defined in Table 12.3-1 shall have the effects accounted for by multiplying M_{ta} at each level by a torsional amplification factor, A_x, as illustrated in Figure 12.8-1 and determined from the following equation:

$$A_x = \left(\frac{\delta_{max}}{1.2\delta_{avg}}\right)^2 \qquad (12.8\text{-}15)$$

where δ_{max} is the maximum displacement [in. (mm)] at level x, computed assuming $A_x = 1$, and δ_{avg} is the average of the displacements [in. (mm)] at the extreme points of the structure at level x, computed assuming $A_x = 1$.

For the purpose of computing δ_{max} and δ_{avg}, it shall be permitted to assume the diaphragm is rigid. The torsional amplification factor, A_x, shall not be less than 1 and is not required to exceed 3.0. The more severe loading for each element shall be considered for design.

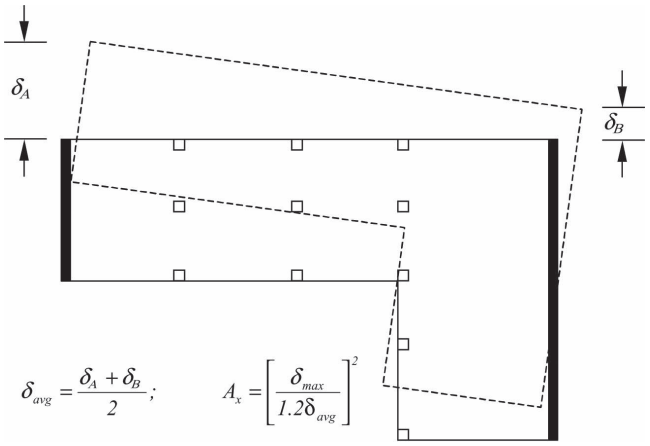

Figure 12.8-1. Torsional amplification factor, A_x.

12.8.5 Overturning The structure shall be designed to resist overturning effects caused by the seismic forces determined in Section 12.8.3.

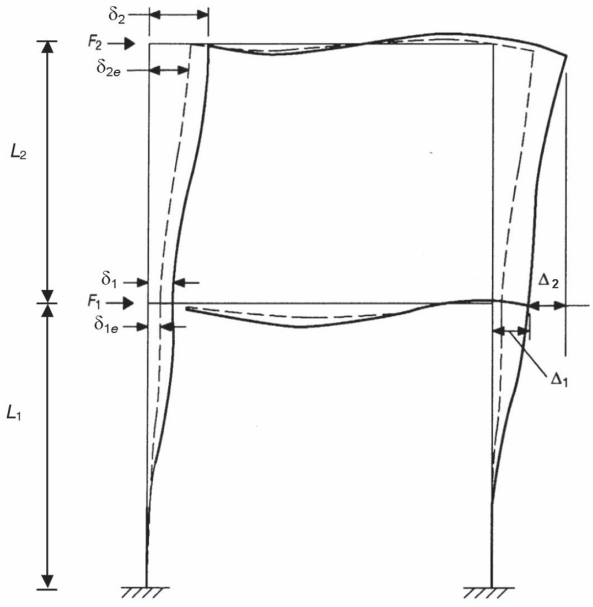
12.8.6 Displacement and Drift Determination Displacements and drifts shall be determined as required by this section.

12.8.6.1 Minimum Base Shear and Load Combination for Computing Displacement and Drift The elastic analysis of the seismic force-resisting system for computing displacement and drift shall be made using the prescribed seismic design forces of Section 12.8 using a load factor of 1.0 on E_h, in the presence of expected gravity loads. Expected gravity loads shall be taken as no less than $1.0D + 0.5L$, L shall be taken as $0.8L_0$ for live loads that exceed 100 lb/ft^2 (4.79 kN/m^2) and $0.4L_0$ for all other live loads, and L_0 is the unreduced design live load (see Table 4-1).

EXCEPTION: Equation (12.8-6) need not be considered for computing drift.

12.8.6.2 Period for Computing Displacement and Drift For determining displacements and drifts, it is permitted to determine the elastic displacements, δ_e, using seismic design forces based on the computed fundamental period of the structure without the upper limit, C_uT_a, specified in Section 12.8.2.

12.8.6.3 Design Earthquake Displacement The Design Earthquake Displacement, δ_{DE}, shall be determined at the location of an element or component using Equation (12.8-16) or as permitted in Chapter 16, 17, or 18.



$$\delta_{DE} = \frac{C_d\delta_e}{I_e} + \delta_{di} \qquad (12.8\text{-}16)$$

where

C_d = Deflection amplification factor in Table 12.2-1.
I_e = Importance Factor determined in accordance with Section 11.5.1;
δ_e = Elastic displacement computed under design earthquake forces, including the effects of accidental torsion and torsional amplification as applicable; and
δ_{di} = Displacement due to diaphragm deformation corresponding to the design earthquake, including Section 12.10 diaphragm forces.

12.8.6.4 Maximum Considered Earthquake Displacement The Maximum Considered Earthquake Displacement, δ_{MCE}, shall be determined at the location under consideration using Equation (12.8-17) or as permitted in Chapter 16, 17, or 18.

@seismicisolation

Note: Δ_i = story drift; Δ_i / L_i = story drift ratio; δ_x = total displacement; i = level under consideration.

Story Level 1: F_1 = strength-level design earthquake force; δ_{1e} = elastic displacement computed under strength-level design earthquake forces; $\delta_1 = C_d \delta_{1e} / I_E$ = amplified displacement; $\Delta_1 = \delta_1 \le \Delta_a$ (Table 12.12-1).

Story Level 2: F_2 = strength-level design earthquake force; δ_{2e} = elastic displacement computed under strength-level design earthquake forces; $\delta_2 = C_d \delta_{2e} / I_E$ = amplified displacement; $\Delta_2 = C_d(\delta_{2e} - \delta_{1e}) / I_E \le \Delta_a$ (Table 12.12-1).

Figure 12.8-2. Story drift determination.

$$\delta_{MCE} = 1.5 \left[\frac{R\delta_e}{I_e} + \delta_{di} \right] \qquad (12.8\text{-}17)$$

where R is the response modification coefficient in Table 12.2-1.

12.8.6.5 Design Story Drift Determination The Design Story Drift, Δ, shall be computed as the difference of the Design Earthquake Displacements, δ_{DE}, as determined in accordance with Section 12.8.6, at the centers of mass at the top and bottom of the story under consideration. Where centers of mass do not align vertically, it is permitted to compute the deflection at the bottom of the story based on the vertical projection of the center of mass at the top of the story.

Diaphragm deformation may be neglected in determining the design story drift. Diaphragm rotation shall be considered as follows. For structures assigned to Seismic Design Category C, D, E, or F that have horizontal irregularity Type 1 of Table 12.3-1, the design story drift, Δ, shall be computed as the largest difference of the Design Earthquake Displacements of vertically aligned points at the top and bottom of the story under consideration along any of the edges of the structure, including the effects of diaphragm rotation.

12.8.7 P-Delta Effects P-delta effects on story shears and moments, the resulting member forces and moments, and the story drifts induced by these effects are not required to be considered where the stability coefficient, θ, as determined by the following equation is equal to or less than 0.10:

$$\theta = \frac{P_x / h_{sx}}{V_x / \Delta_{xe}} \qquad (12.8\text{-}18)$$

where

P_x = Total vertical design load [kip (kN)] at and above level x per Section 12.8.6.1 (where computing P_x, no individual load factor need exceed 1.0);

V_x / Δ_{xe} = Story stiffness at level x [kip/in (kN/mm)], calculated as the ratio of the seismic design shear, V_x, divided by the corresponding elastic story drift, Δ_{xe}; and

h_{sx} = Story height below level x [in. (mm)].

The story stiffness, V_x / Δ_{xe}, shall be computed at the location required for the design story drift per Section 12.8.6.5 and may be determined without consideration of diaphragm deformation.

The stability coefficient, θ, shall not exceed θ_{max}, determined as follows:

$$\theta_{max} = \frac{0.5}{\beta C_d} \le 0.25 \qquad (12.8\text{-}19)$$

where C_d is the deflection amplification factor in Table 12.2-1, and β is the ratio of shear demand to design shear capacity for the story between levels x and $x - 1$. The value of β is permitted to be conservatively taken as 1.0, and shall not be taken less than $1.25/\Omega_0$. The value of θ_{max} determined from Equation (12.8-19) need not be taken less than 0.1.

Where the stability coefficient, θ, is greater than 0.10 but less than or equal to θ_{max}, the incremental factor related to P-delta effects on displacements and member forces shall be determined by rational analysis. Alternatively, it is permitted to multiply displacements and member forces by $1.0/(1 - \theta)$. Where θ is greater than θ_{max}, the structure is potentially unstable and shall be redesigned. Where the P-delta effect is included in an automated analysis, Equation (12.8-19) shall still be satisfied; however, the value of θ computed from Equation (12.8-18) using the results of the P-delta analysis is permitted to be divided by $(1 + \theta)$ before checking Equation (12.8-19).

12.9 LINEAR DYNAMIC ANALYSIS

12.9.1 Modal Response Spectrum Analysis

12.9.1.1 Number of Modes An analysis shall be conducted to determine the natural modes of vibration for the structure. The analysis shall include a sufficient number of modes to obtain a combined modal mass participation of 100% of the structure's mass. For this purpose, it shall be permitted to represent all modes with periods less than 0.05 s in a single rigid body mode that has a period of 0.05 s.

EXCEPTION: Alternatively, the analysis shall be permitted to include a minimum number of modes to obtain a combined modal mass participation of at least 90% of the actual mass in each orthogonal horizontal direction of response considered in the model.

12.9.1.2 Modal Response Parameters The value for each force-related design parameter of interest, including story drifts, support forces, and individual member forces for each mode of response, shall be computed using the properties of each mode and the response spectra defined in either Section 11.4.5 divided by the quantity R/I_e. The value for displacement and drift quantities shall be multiplied by the quantity C_d/I_e.

12.9.1.3 Combined Response Parameters The value for each parameter of interest calculated for the various modes shall be combined using the square root of the sum of the squares (SRSS)

@seismicisolation

method, the complete quadratic combination (CQC) method, the complete quadratic combination method as modified by ASCE 4 (CQC-4), or an approved equivalent approach. The CQC or the CQC-4 method shall be used for each of the modal values where closely spaced modes have significant cross-correlation of translational and torsional response.

12.9.1.4 Scaling Design Values of Combined Response A base shear, V, shall be calculated in each of the two orthogonal horizontal directions using the calculated fundamental period of the structure, T, in each direction and the procedures of Section 12.8.

12.9.1.4.1 Scaling of Forces Where the calculated fundamental period exceeds $C_u T_a$ in a given direction, $C_u T_a$ shall be used in lieu of T in that direction. Where the combined response for the modal base shear, V_t, is less than 100% of the calculated base shear, V, using the equivalent lateral force procedure, the forces shall be multiplied by V/V_t, where V is the equivalent lateral force procedure base shear, calculated in accordance with this section and Section 12.8, and V_t is the base shear from the required modal combination.

12.9.1.4.2 Scaling of Drifts Where the combined response for the modal base shear, V_t, is less than $C_s W$, and where C_s is determined in accordance with Equation (12.8-7), displacements shall be multiplied by $C_s W/V_t$.

12.9.1.5 Horizontal Shear Distribution The distribution of horizontal shear shall be in accordance with Section 12.8.4, The effects of accidental torsion shall be accounted for by applying a static accidental torsional moment, M_{ta}, determined in accordance with Sections 12.8.4.2 and 12.8.4.3, to the mathematical model, and combining the results with the scaled design values computed in accordance with Section 12.9.1.4.

EXCEPTION: For structures without a horizontal irregularity Type 1, the effects of accidental torsion may be included in the dynamic analysis model in lieu of applying M_{ta}. When the effects of accidental torsion are included in the dynamic analysis model and TIR $\leq$ 1.6, amplification of torsion in accordance with Section 12.8.4.3 is not required. If TIR > 1.6, accidental torsion shall be added as a static load case in accordance with Section 12.8.4.3.

12.9.1.6 P-Delta Effects The P-delta effects shall be determined in accordance with Section 12.8.7. The base shear used to determine the displacement and drifts shall be determined in accordance with Section 12.8.6.

12.9.1.7 Soil–Structure Interaction Reduction A soil–structure interaction reduction is permitted where determined using Chapter 19 or other generally accepted procedures approved by the Authority Having Jurisdiction.

12.9.1.8 Structural Modeling A mathematical model of the structure shall be constructed in accordance with Section 12.7.3, except that all structures designed in accordance with this section shall be analyzed using a three dimensional (3D) representation. Where the diaphragms have not been classified as rigid in accordance with Section 12.3.1, the model shall include representation of the diaphragm's stiffness characteristics and additional dynamic degrees of freedom as required to account for the participation of the diaphragm in the structure's dynamic response.

12.9.2 Linear Response History Analysis

12.9.2.1 General Requirements Linear response history analysis shall consist of an analysis of a linear mathematical model of the structure to determine its response through methods of numerical integration, to suites of spectrally matched acceleration histories compatible with the design response spectrum for the site. The analysis shall be performed in accordance with the requirements of this section.

12.9.2.2 General Modeling Requirements Three-dimensional (3D) models of the structure shall be required. Modeling the distribution of stiffness and mass throughout the structure's lateral load-resisting system and diaphragms shall be in accordance with Section 12.7.3.

12.9.2.2.1 P-Delta Effects The mathematical model shall include P-delta effects. Limits on the stability coefficient, θ, shall be satisfied in accordance with Section 12.8.7.

12.9.2.2.2 Accidental Torsion Accidental torsion, where required by Section 12.8.4.2, shall be included by offsetting the center of mass in each direction (i.e., plus or minus) from its expected location by a distance equal to 5% of the horizontal dimension of the structure at the given floor measured perpendicular to the direction of loading. Amplification of accidental torsion in accordance with Section 12.8.4.3 is not required.

12.9.2.2.3 Foundation Modeling Where foundation flexibility is included in the analysis, modeling of the foundation shall be in accordance with Section 12.13.3.

12.9.2.2.4 Number of Modes to Include in Modal Response History Analysis Where the modal response history analysis procedure is used, the number of modes to include in the analysis shall be in accordance with Section 12.9.1.1.

12.9.2.2.5 Damping Linear viscous damping shall not exceed 5% critical for any mode with a vibration period greater than or equal to T_{lower}.

12.9.2.3 Ground Motion Selection and Modification Ground acceleration histories used for analysis shall consist of a suite of no fewer than three pairs of spectrally matched orthogonal components derived from artificial or recorded ground motion events. The target response spectrum for each spectrally matched set shall be developed in accordance with Sections 11.4.6 or 21.3, as applicable.

12.9.2.3.1 Procedure for Spectrum Matching Each component of ground motion shall be spectrally matched over the period range $0.8T_{lower}$ to $1.2T_{upper}$. Over the same period range and in each direction of response, the average of the 5% damped pseudoacceleration ordinates computed using the spectrum-matched records shall not fall above or below the target spectrum by more than 10% in each direction of response.

12.9.2.4 Application of Ground Acceleration Histories Two orthogonal directions of response, designated as X and Y, shall be selected and used for all response history analysis. Ground motions shall be applied independently in the X and Y directions.

12.9.2.5 Modification of Response for Design

12.9.2.5.1 Determination of Maximum Elastic and Inelastic Base Shear For each ground motion analyzed, a maximum elastic base shear, designated as V_{EX} and V_{EY} in the X and Y directions, respectively, shall be determined. The mathematical model used for computing the maximum elastic base shear shall not include accidental torsion.

For each ground motion analyzed, a maximum inelastic base shear, designated as V_{IX} and V_{IY} in the X and Y directions, respectively, shall be determined as follows:

@seismicisolation

$$V_{IX} = \frac{V_{EX} I_e}{R_X} \quad (12.9\text{-}1)$$

$$V_{IY} = \frac{V_{EY} I_e}{R_Y} \quad (12.9\text{-}2)$$

where I_e is the Importance Factor and R_X and R_Y are the response modification coefficients for the X and Y directions, respectively.

12.9.2.5.2 Determination of Base Shear Scale Factor Design base shears, V_X and V_Y, shall be computed in the X and Y directions, respectively, in accordance with Section 12.8.1. For each ground motion analyzed, base shear scale factors in each direction of response shall be determined as follows:

$$\eta_X = \frac{V_X}{V_{IX}} \geq 1.0 \quad (12.9\text{-}3)$$

$$\eta_Y = \frac{V_Y}{V_{IY}} \geq 1.0 \quad (12.9\text{-}4)$$

12.9.2.5.3 Determination of Combined Force Response For each direction of response and for each ground motion analyzed, the combined force response shall be determined as follows:

(a) The combined force response in the X direction shall be determined as $I_e\eta_X/R_X$ times the computed elastic response in the X direction using the mathematical model with accidental torsion (where required) plus $I_e\eta_Y/R_Y$ times the computed elastic response in the Y direction using the mathematical model without accidental torsion.

(b) The combined force response in the Y direction shall be determined as $I_e\eta_Y/R_Y$ times the computed elastic response in the Y direction using the mathematical model with accidental torsion (where required), plus $I_e\eta_X/R_X$ times the computed elastic response in the X direction using the mathematical model without accidental torsion.

12.9.2.5.4 Determination of Combined Displacement Response Response modification factors C_{dX} and C_{dY} shall be assigned in the X and Y directions, respectively. For each direction of response and for each ground motion analyzed, the combined displacement responses shall be determined as follows:

(a) The combined displacement response in the X direction shall be determined as $\eta_X C_{dX}/R_X$ times the computed elastic response in the X direction using the mathematical model with accidental torsion (where required), plus $\eta_Y C_{dY}/R_Y$ times the computed elastic response in the Y direction using the mathematical model without accidental torsion.

(b) The combined displacement response in the Y direction shall be determined as $\eta_Y C_{dY}/R_Y$ times the computed elastic response in the Y direction using the mathematical model with accidental torsion (where required), plus $\eta_X C_{dX}/R_X$ times the computed elastic response in the X direction using the mathematical model without accidental torsion.

EXCEPTION: Where the design base shear in the given direction is not controlled by Equation (12.8-7), the factors η_X or η_Y, as applicable, are permitted to be taken as 1.0 for the purpose of determining combined displacements.

12.9.2.6 Enveloping of Force Response Quantities Design force response quantities shall be taken as the envelope of the combined force response quantities computed in both orthogonal directions and for all ground motions considered. Where force interaction effects are considered, demand to capacity ratios are permitted to be enveloped in lieu of individual force quantities.

12.9.2.7 Enveloping of Displacement Response Quantities Story drift quantities shall be determined for each ground motion analyzed and in each direction of response using the combined displacement responses defined in Section 12.9.2.5.4. For the purpose of complying with the drift limits specified in Section 12.12, the envelope of story drifts computed in both orthogonal directions and for all ground motions analyzed shall be used.

12.10 DIAPHRAGMS, CHORDS, AND COLLECTORS

Diaphragms, chords, and collectors shall be designed in accordance with Sections 12.10.1 and 12.10.2.

EXCEPTIONS:

(a) Precast concrete diaphragms, including chords and collectors in structures assigned to Seismic Design Category C, D, E, or F, shall be designed in accordance with Section 12.10.3.

(b) Precast concrete diaphragms in Seismic Design Category B, cast-in-place concrete diaphragms, cast-in-place concrete equivalent precast diaphragms, and wood-sheathed diaphragms supported by wood diaphragm framing, bare steel deck diaphragms, and concrete-filled steel deck diaphragms are permitted to be designed in accordance with Section 12.10.3.

(c) Diaphragms, chords, and collectors in one-story structures that conform to the limitations of Section 12.10.4.1 are permitted to be designed in accordance with Section 12.10.4.

12.10.1 Diaphragm Design Diaphragms shall be designed for both the shear and the bending stresses resulting from design forces. At diaphragm discontinuities, such as openings and reentrant corners, the design shall ensure that the dissipation or transfer of edge (chord) forces, combined with other forces in the diaphragm, is within the shear and tension capacity of the diaphragm.

12.10.1.1 Diaphragm Design Forces Floor and roof diaphragms shall be designed to resist in-plane seismic design forces from the structural analysis but shall not be less than that determined in accordance with Equation (12.10-1) as follows:

$$F_{px} = \frac{\sum_{n}^{i=x} F_i}{\sum_{n}^{i=x} w_i} w_{px} \quad (12.10\text{-}1)$$

where

F_{px} = Diaphragm design force at level x;
F_i = Design force applied to level i;
w_i = Weight tributary to level i; and
w_{px} = Weight tributary to the diaphragm at level x.

The force determined from Equation (12.10-1) shall not be less than

$$F_{px} = 0.2 S_{DS} I_e w_{px} \quad (12.10\text{-}2)$$

@seismicisolation

The force determined from Equation (12.10-1) need not exceed

$$F_{px} = 0.4 S_{DS} I_e w_{px} \quad (12.10\text{-}3)$$

Diaphragms shall be designed for the inertial forces determined from Equations (12.10-1) through (12.10-3) and for applicable transfer forces resisted by the diaphragm between vertical seismic force-resisting elements. For structures that have a horizontal structural irregularity of Type 4 in Table 12.3-1, the transfer forces between horizontally offset vertical seismic force-resisting elements shall be increased by the overstrength factor of Section 12.4.3 before being added to the diaphragm inertial forces. For structures that have horizontal or vertical structural irregularities of the types indicated in Section 12.3.3.5, the requirements of that section shall also apply.

EXCEPTION: One- and two-family dwellings of light-frame construction shall be permitted to use $\Omega_0 = 1.0$.

12.10.2 Collector Elements Collector elements shall be provided that are capable of transferring the seismic forces originating in other portions of the structure to the element providing the resistance to those forces.

12.10.2.1 Collector Elements Requiring Load Combinations Including Overstrength for Seismic Design Categories C through F In structures assigned to Seismic Design Category C, D, E, or F, collector elements (Figure 12.10-1) and their connections, including connections to vertical elements, shall be designed to resist the maximum of the following:

(a) Forces calculated using the seismic load effects including overstrength of Section 12.4.3 with seismic forces determined by the equivalent lateral force procedure of Section 12.8 or the modal response spectrum analysis procedure of Section 12.9.1;
(b) Forces calculated using the seismic load effects including overstrength of Section 12.4.3 with seismic forces determined by Equation (12.10-1); and
(c) Forces calculated using the load combinations of Section 2.3.6 with seismic forces determined by Equation (12.10-2).

Transfer forces as described in Section 12.10.1.1 shall be considered.

EXCEPTION: In structures or portions thereof braced entirely by wood light-frame shear walls, collector elements and their connections, including connections to vertical elements, need only be designed to resist forces using the load combinations of Section 2.3.6 with seismic forces determined in accordance with Section 12.10.1.1.

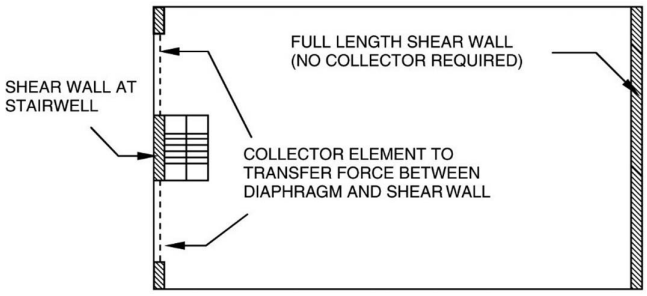


Figure 12.10-1. Collectors.

12.10.3 Alternative Design Provisions for Diaphragms, Including Chords and Collectors Where required or permitted in Section 12.10, diaphragms, including chords and collectors, shall be designed using the provisions in Sections 12.10.3.1 through 12.10.3.5 and the following:

1. Footnote *b* to Table 12.2-1 shall not apply.
2. Section 12.3.3.5 shall not apply.
3. Section 12.3.4.1, Item 5, shall be replaced with the following: "Design of diaphragms, including chords, collectors, and their connections to the vertical elements" are used.
4. Section 12.3.4.1, Item 7, shall not apply.

12.10.3.1 Design Diaphragms, including chords, collectors, and their connections to the vertical elements, shall be designed in two orthogonal directions to resist the in-plane design seismic forces determined in Section 12.10.3.2. Collectors shall be provided that are capable of transferring the seismic forces originating in other portions of the structure to the vertical elements providing the resistance to those forces. Design shall provide for transfer of forces at diaphragm discontinuities, such as openings and reentrant corners.

12.10.3.2 Seismic Design Forces for Diaphragms, Including Chords and Collectors Diaphragms, including chords, collectors, and their connections to the vertical elements, shall be designed to resist in-plane seismic design forces given by Equation (12.10-4):

$$F_{px} = \frac{C_{px}}{R_s} w_{px} \quad (12.10\text{-}4)$$

The force F_{px} determined from Equation (12.10-4) shall not be less than:

$$F_{px} = 0.2 S_{DS} I_e w_{px} \quad (12.10\text{-}5)$$

C_{px} shall be determined as illustrated in Figure 12.10-2.

12.10.3.2.1 Design Acceleration Coefficients C_{p0}, C_{pi}, and C_{pn} Design acceleration coefficients C_{p0} and C_{pn} shall be calculated by Equations (12.10-6) and (12.10-7):

$$C_{p0} = 0.4 S_{DS} I_e \quad (12.10\text{-}6)$$

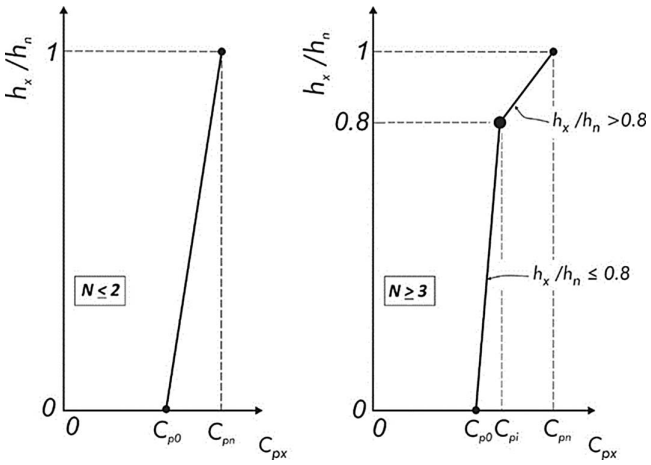

Figure 12.10-2. Calculating the design acceleration coefficient, C_{px}, in buildings with $N \leq 2$ and in buildings with $N \geq 3$.

@seismicisolation

and

$$C_{pn} = \sqrt{(\Gamma_{m1}\Omega_0 C_s)^2 + (\Gamma_{m2} C_{s2})^2} \geq C_{pi} \qquad (12.10\text{-}7)$$

Design acceleration coefficient, C_{pi}, shall be the greater of the values given by Equations (12.10-8) and (12.10-9):

$$C_{pi} = 0.8 C_{p0} \qquad (12.10\text{-}8)$$

$$C_{pi} = 0.9 \Gamma_{m1} \Omega_0 C_s \qquad (12.10\text{-}9)$$

where Ω_0 is the overstrength factor given in Table 12.2-1; C_s is determined in accordance with Section 12.8 or 12.9; and C_{s2} shall be the smallest of the values calculated from Equations (12.10-10), (12.10-11), and (12.10-12).

$$C_{s2} = (0.15N + 0.25) I_e S_{DS} \qquad (12.10\text{-}10)$$

$$C_{s2} = I_e S_{DS} \qquad (12.10\text{-}11)$$

$$\text{For } N \geq 2 \quad C_{s2} = \frac{I_e S_{D1}}{0.03(N-1)} \qquad (12.10\text{-}12a)$$

$$\text{For } N = 1 \quad C_{s2} = 0 \qquad (12.10\text{-}12b)$$

The modal contribution factors Γ_{m1} and Γ_{m2} in Equation (12.10-7) shall be calculated from Equations (12.10-13) and (12.10-14).

$$\Gamma_{m1} = 1 + \frac{z_s}{2}\left(1 - \frac{1}{N}\right) \qquad (12.10\text{-}13)$$

and

$$\Gamma_{m2} = 0.9 z_s \left(1 - \frac{1}{N}\right)^2 \qquad (12.10\text{-}14)$$

where the mode shape factor, z_s, is to be taken as 0.3 for buildings designed with buckling restrained braced frame systems defined in Table 12.2-1; 0.7 for buildings designed with moment-resisting frame systems defined in Table 12.2-1; 0.85 for buildings designed with dual systems defined in Table 12.2-1 with special or intermediate moment frames capable of resisting at least 25% of the prescribed seismic forces; and 1.0 for buildings designed with all other seismic force-resisting systems.

12.10.3.3 Transfer Forces in Diaphragms Diaphragms designed in accordance with this section shall be designed for the inertial forces determined from Equations (12.10-4) and (12.10-5) and for applicable transfer forces acting through the diaphragm between vertical seismic force-resisting elements. For structures that have a horizontal structural irregularity of Type 4 in Table 12.3-1, the transfer forces between horizontally offset vertical seismic force-resisting elements shall be increased by the overstrength factor of Section 12.4.3 before being added to the diaphragm inertial forces. For structures that have other horizontal or vertical structural irregularities of the types indicated in Section 12.3.3.5, the requirements of that section shall also apply.

EXCEPTION: One- and two-family dwellings of light-frame construction shall be permitted to use $\Omega_0 = 1.0$.

12.10.3.4 Collectors—Seismic Design Categories C through F In structures assigned to Seismic Design Category C, D, E, or F, collectors and their connections, including connections to vertical elements, shall be designed to resist 1.5 times the diaphragm inertial forces from Section 12.10.3.2 plus 1.5 times the design transfer forces.

EXCEPTIONS:

1. Any transfer force increased by the overstrength factor of Section 12.4.3 need not be further amplified by 1.5.
2. For moment frame and braced frame systems, collector forces need not exceed the lateral strength of the corresponding frame line below the collector, considering only the moment frames or braced frames. In addition, diaphragm design forces need not exceed the forces corresponding to the collector forces so determined.
3. In structures or portions thereof braced entirely by light-frame shear walls, collector elements and their connections, including connections to vertical elements, need only be designed to resist the diaphragm seismic design forces, without the 1.5 multiplier.

12.10.3.5 Diaphragm Design Force Reduction Factor The diaphragm design force reduction factor, R_s, shall be determined in accordance with Table 12.10-1.

12.10.4 Alternative Diaphragm Design Provisions for One-Story Structures with Flexible Diaphragms and Rigid Vertical Elements Where permitted by Section 12.10 and subject to the limitations of Section 12.10.4.1, diaphragm design forces, including design forces for chords, collectors, and their in-plane connections to vertical elements, shall be determined in accordance with Section 12.10.4.2.

12.10.4.1 Limitations Diaphragms in one-story structures are permitted to be designed in accordance with Section 12.10.4 provided all of the following limitations are satisfied.

1. All portions of the diaphragm shall be designed using the provisions of this section in both orthogonal directions.
2. The diaphragm shall consist of either (a) a wood structural panel diaphragm designed in accordance with AWC SDPWS and fastened to wood framing members or wood nailers with sheathing nailing in accordance with the AWC SDPWS Section 4.2 nominal shear capacity tables, or (b) a bare (untopped) steel deck diaphragm meeting the requirements of AISI S400 and AISI S310.
3. Toppings of concrete or similar materials that affect diaphragm strength or stiffness shall not be placed over the wood structural panel or bare steel deck diaphragm.
4. The diaphragm shall not contain horizontal structural irregularities, as specified in Table 12.3-1, except that Horizontal Structural Irregularity Type 2 is permitted.
5. The diaphragm shall be rectangular in shape or shall be divisible into rectangular segments for purpose of seismic design, with vertical elements of the seismic force-resisting system or collectors provided at each end of each rectangular segment span.
6. The vertical elements of the seismic force-resisting system shall be limited to one or more of the following: concrete shear walls, precast concrete shear walls, masonry shear walls, steel concentrically braced frames, steel and concrete composite braced frames, or steel and concrete composite shear walls.
7. The vertical elements of the seismic force-resisting system shall be designed in accordance with Section 12.8, except that they shall be permitted to be designed using the two-stage analysis procedure of Section 12.2.3.4, where applicable.

@seismicisolation

Table 12.10-1. Diaphragm Design Force Reduction Factor, R_s.

Diaphragm System		Shear-Controlled	Flexure-Controlled
Cast-in-place concrete designed in accordance with ACI 318	—	1.5	2
Precast concrete designed in accordance with ACI 318	Elastic design option	0.7	0.7
	Basic design option	1.0	1.0
	Reduced design option	1.4	1.4
Wood sheathed designed in accordance with Section 14.5 and AWC SDPWS	—	3.0	NA*
Bare steel deck diaphragm designed in accordance with Section 14.1.5	With special seismic detailing	2.5	NA*
	Other	1.0	NA*
Concrete-filled steel deck diaphragm designed in accordance with Section 14.1.6	—	2.0	NA*

*Not Applicable

12.10.4.2 Design Diaphragms, including chords, collectors, and their connections to vertical elements, shall be designed in two orthogonal directions to resist the in-plane design seismic forces determined in accordance with this section. Multi-span diaphragms and diaphragms that are not rectangular in shape shall be divided into rectangular segments for purposes of design in accordance with this section, with lateral support provided at each end of each diaphragm segment span by a vertical element or collector element.

12.10.4.2.1 Seismic Design Forces The diaphragm seismic design force, F_{px}, shall be determined in accordance with Equation (12.10-15).

$$F_{px} = C_{s-\text{diaph}}(w_{px}) \tag{12.10-15}$$

where

w_{px} = The effective seismic weight tributary to the diaphragm, and $C_{\text{s-diaph}}$ is calculated as

$$C_{s-\text{diaph}} = \frac{S_{DS}}{\frac{R_{\text{diaph}}}{I_e}} \tag{12.10-16a}$$

and need not be greater than

$$C_{s-\text{diaph}} = \frac{S_{D1}}{T_{\text{diaph}}\left(\frac{R_{\text{diaph}}}{I_e}\right)} \tag{12.10-16b}$$

where

S_{DS} = Design spectral response parameter in the short period range as determined from Section 11.4.5 or 11.4.8;

R_{diaph} = 4.5 for wood structural panel diaphragms, 4.5 for bare steel deck diaphragms that meet the special seismic detailing requirements of AISI S400, and 1.5 for all other bare steel deck diaphragms;

I_e = Importance Factor determined in accordance with Section 11.5.1; and

T_{diaph} = $0.002L_{\text{diaph}}$ for wood structural panel diaphragms, or $0.001L_{\text{diaph}}$ for profiled steel deck panel diaphragms, determined for each rectangular segment of the diaphragm in each orthogonal direction [seconds].

12.10.4.2.2 Diaphragm Shears Diaphragm design shears shall be computed for each diaphragm segment in accordance with Section 12.10.4.2.1. Where the diaphragm segment span, L_{diaph}, is less than 100 ft (30.5 m), the diaphragm design shear, from loading perpendicular to the span, shall be the diaphragm shear calculated using the F_{px} forces of Section 12.10.4.2.1 multiplied by 1.5. Where the diaphragm segment span, L_{diaph}, is greater than or equal to 100 ft (30.5 m), the diaphragm design shear shall be amplified to 1.5 times the shear calculated using the F_{px} forces of Section 12.10.4.2.1, over an amplified shear boundary zone having a minimum width of 10% of the diaphragm segment span, L_{diaph}. The amplified shear boundary zone shall be provided at each supporting end of the diaphragm segment span under consideration.

12.10.4.2.3 Diaphragm Chords Diaphragm chords shall be provided at each edge of each diaphragm segment to resist tension and compression forces resulting from diaphragm moments. Diaphragm chord forces shall be computed using the F_{px} forces of Section 12.10.4.2.1.

12.10.4.2.4 Collector Elements and Their Connections Collector elements shall be provided that are capable of transferring the seismic forces originating in other portions of the structure to the vertical elements of the seismic force-resisting system. Collector element forces shall be computed using the F_{px} forces of Section 12.10.4.2.1. Collectors and their connections to vertical elements of the seismic force-resisting system in structures assigned to Seismic Design Categories C through F shall be designed to resist the forces calculated using the seismic load effects including overstrength factor of Section 12.4.3, with diaphragm overstrength factor, $\Omega_{\text{0-diaph}}$, taken equal to 2; however, $W_{\text{0-diaph}}$ need not exceed R_{diaph}. This need not be combined with the shear amplification of 1.5 specified in Section 12.10.4.2.2.

12.10.4.2.5 Diaphragm Deflection Where required by this standard, the deflection amplification factor, $C_{\text{d-diaph}}$, for diaphragm deflection shall be taken as one of the following:

$C_{\text{d-diaph}}$ = 3.0 for wood structural panel diaphragms,
= 3.0 for bare steel deck diaphragms that meet the special seismic detailing requirements of AISI S400, and
= 1.5 for all other bare steel deck diaphragms.

Diaphragm deflections shall be calculated using Section 12.10.4.2.1 seismic design forces.

12.10.4.2.6 Modifications to Diaphragm Seismic Design For structures in which the diaphragm design forces are determined in accordance with Section 12.10.4, footnote *b* to Table 12.2-1 shall not apply, and Section 12.3.3.5 shall not apply.

@seismicisolation
@seismicisolation

12.11 STRUCTURAL WALLS AND THEIR ANCHORAGE

12.11.1 Design for Out-of-Plane Forces Structural walls shall be designed for a force normal to the surface equal to $F_p = 0.4 S_{DS} I_e$ times the weight of the structural wall with a minimum force of 10% of the weight of the structural wall.

12.11.2 Anchorage of Structural Walls and Transfer of Design Forces into Diaphragms or Other Supporting Structural Elements

12.11.2.1 Wall Anchorage Forces The anchorage of structural walls to supporting construction shall provide a direct connection capable of resisting the following:

$$F_p = 0.4 S_{DS} k_a I_e W_p \tag{12.11-1}$$

where

F_p = Design force in the individual anchors;
S_{DS} = Design spectral response acceleration parameter at short periods per Section 11.4.5;
I_e = Importance Factor determined in accordance with Section 11.5.1;
k_a = Amplification factor for diaphragm flexibility;
L_f = Span, in feet, of a flexible diaphragm that provides the lateral support for the wall (the span is measured between vertical elements that provide lateral support to the diaphragm in the direction considered; use zero for rigid diaphragms); and
W_p = Weight of the wall tributary to the anchor.

F_p shall not be taken as less than the larger of $0.2 k_a I_e W_p$ and 5 lb/ft^2 (0.24 kN/m^2) times the area of the wall tributary to the anchor.

$$k_a = 1.0 + \frac{L_f}{100} \tag{12.11-2}$$

but k_a need not be taken as larger than 2.0, and need not be taken as larger than 1.0 when the connection is not at a flexible diaphragm.

Where the anchorage is not located at the roof and all diaphragms are not flexible, the value from Equation (12.11-1) is permitted to be multiplied by the factor $(1 + 2z/h)/3$, where z is the height of the anchor above the base of the structure, and h is the height of the roof above the base; however, F_p shall not be less than required by Section 12.11.1 with a minimum anchorage force of $F_p = 0.2 W_p$ but not less than 5 lb/ft^2 (0.24 kN/m^2) times the area of the wall tributary to the anchor.

Structural walls shall be designed to resist bending between anchors where the anchor spacing exceeds 4 ft (1,219 mm). Interconnection of structural wall elements and connections to supporting framing systems shall have sufficient strength, rotational capacity, and ductility to resist shrinkage, thermal changes, and differential foundation settlement when combined with seismic forces.

12.11.2.2 Additional Requirements for Anchorage of Concrete or Masonry Structural Walls to Diaphragms in Structures Assigned to Seismic Design Categories C through F

12.11.2.2.1 Transfer of Anchorage Forces into Diaphragm Diaphragms shall be provided with continuous ties or struts between diaphragm chords to distribute these anchorage forces into the diaphragms. Diaphragm connections shall be positive, mechanical, or welded. Added chords are permitted to be used to form subdiaphragms to transmit the anchorage forces to the main continuous crossties. The maximum length-to-width ratio of structural subdiaphragms that serve as part of the continuous tie system shall be 2.5 to 1. Connections and anchorages capable of resisting the prescribed forces shall be provided between the diaphragm and the attached components. Connections shall extend into the diaphragm a sufficient distance to develop the force transferred into the diaphragm.

12.11.2.2.2 Steel Elements of Structural Wall Anchorage System The strength design forces for steel elements of the structural wall anchorage system, with the exception of anchor bolts and reinforcing steel, shall be increased by 1.4 times the forces otherwise required by this section.

12.11.2.2.3 Wood Diaphragms The anchorage of concrete or masonry structural walls to wood diaphragms shall be in accordance with AWC SDPWS 4.1.5.1 and this section. Continuous ties required by this section shall be in addition to the diaphragm sheathing. Anchorage shall not be accomplished by use of toenails or nails subject to withdrawal, nor shall wood ledgers or framing be used in cross-grain bending or cross-grain tension. The diaphragm sheathing shall not be considered effective for providing the ties or struts required by this section.

12.11.2.2.4 Metal Deck Diaphragms In metal deck diaphragms, the metal deck shall not be used as the continuous ties required by this section in the direction perpendicular to the deck span.

12.11.2.2.5 Embedded Straps Diaphragm to structural wall anchorage using embedded straps shall be attached to, or hooked around, the reinforcing steel or otherwise terminated so as to effectively transfer forces to the reinforcing steel.

12.11.2.2.6 Eccentrically Loaded Anchorage System Where elements of the wall anchorage system are loaded eccentrically or are not perpendicular to the wall, the system shall be designed to resist all components of the forces induced by the eccentricity.

12.11.2.2.7 Walls with Pilasters Where pilasters are present in the wall, the anchorage force at the pilasters shall be calculated considering the additional load transferred from the wall panels to the pilasters. However, the minimum anchorage force at a floor or roof shall not be reduced.

12.12 DRIFT AND DEFORMATION

12.12.1 Story Drift Limit The design story drift, Δ, as determined in Section 12.8.6, 12.9.1, or 12.9.2 shall not exceed the allowable story drift, Δ_a, as obtained from Table 12.12-1 for any story.

12.12.1.1 Moment Frames in Structures Assigned to Seismic Design Categories D through F For seismic force-resisting systems solely comprising moment frames in structures assigned to Seismic Design Category D, E, or F, the design story drift, Δ, shall not exceed Δ_a/ρ for any story. ρ shall be determined in accordance with Section 12.3.4.2.

12.12.2 Structural Separation All portions of the structure shall be designed and constructed to act as an integral unit in resisting seismic forces unless separated structurally by a distance sufficient to avoid damaging contact as set forth in this section.

Separations shall allow for the Design Earthquake Displacements, δ_{DE}, as determined in accordance with Section 12.8.6.

@seismicisolation

Table 12.12-1. Allowable Story Drift, Δ_a.

Structure	Risk Category		
	I or II	III	IV
Structures, other than masonry shear wall structures, four stories or less above the base as defined in Section 11.2, with interior walls, partitions, and ceilings that have been designed to accommodate the drifts associated with the Design Earthquake Displacements	$0.025h_{sx}$ [a]	$0.020h_{sx}$	$0.015h_{sx}$
Masonry cantilever shear wall structures[b]	$0.010h_{sx}$	$0.010h_{sx}$	$0.010h_{sx}$
Other masonry shear wall structures	$0.007h_{sx}$	$0.007h_{sx}$	$0.007h_{sx}$
All other structures	$0.020h_{sx}$	$0.015h_{sx}$	$0.010h_{sx}$

[a] There shall be no drift limit for single-story structures in which the interior walls, partitions, and ceilings have been designed to accommodate story drifts associated with the Design Earthquake Displacement. The structural separation requirement of Section 12.12.3 is not waived.

[b] Structures in which the basic structural system consists of masonry shear walls designed as vertical elements cantilevered from their base or foundation support that are so constructed that moment transfer between shear walls (coupling) is negligible.

Notes: h_{sx} is the story height below level x. For seismic force-resisting systems solely comprising moment frames in Seismic Design Categories D, E, and F, the allowable story drift shall comply with the requirements of Section 12.12.1.1.

Adjacent structures on the same property shall be separated by at least δ_{SS}, determined as

$$\delta_{SS} = \sqrt{(\delta_{DE1})^2 + (\delta_{DE2})^2} \qquad (12.12\text{-}2)$$

where δ_{DE1} and δ_{DE2} are the Design Earthquake Displacements of the adjacent structures at their adjacent edges. Where a structure adjoins a property line not common to a public way, the structure shall be set back from the property line by at least the displacement δ_{DE} of that structure.

EXCEPTION: Smaller separations or property line setbacks are permitted where justified by rational analysis based on inelastic response to design ground motions.

12.12.3 Members Spanning between Structures Gravity connections or supports for members spanning between structures or seismically separate portions of structures shall be designed for the maximum anticipated relative displacements. These displacements shall be calculated using Maximum Considered Earthquake Displacement (δ_{MCE}), as determined in accordance with Section 12.8.6 and assuming that the two structures are moving in opposite directions and using the absolute sum of the displacements.

12.12.4 Deformation Compatibility for Seismic Design Categories D through F For structures assigned to Seismic Design Category D, E, or F, every structural component not included in the seismic force-resisting system in the direction under consideration shall be designed to be adequate for the gravity load effects and the seismic forces resulting from the Design Earthquake Displacements (δ_{DE}) and the associated drifts as determined in accordance with Section 12.8.6.

EXCEPTION: Reinforced concrete frame members not designed as part of the seismic force-resisting system shall comply with Section 18.14 of ACI 318. Where determining the moments and shears induced in components that are not included in the seismic force-resisting system in the direction under consideration, the stiffening effects of adjoining rigid structural and nonstructural elements shall be considered, and a rational value of member and restraint stiffness shall be used.

12.13 FOUNDATION DESIGN

12.13.1 Design Basis The design basis for foundations shall be as set forth in Section 12.1.5.

12.13.2 Materials of Construction Materials used for the design and construction of foundations shall comply with the requirements of Chapter 14 and the additional requirements of Section 12.13.9 for foundations on liquefiable sites. Design and detailing of steel piles shall comply with Section 14.1.8 and the additional requirements for Section 12.13.9 where applicable. Design and detailing of concrete piles shall comply with ACI 318 and the additional requirements for Section 12.13.9 where applicable.

12.13.3 Foundation Load-Deformation Characteristics Where foundation flexibility is included for the linear analysis procedures in Chapter 12, the load-deformation characteristics of the foundation–soil system shall be modeled in accordance with the requirements of this section. The linear load-deformation behavior of foundations shall be represented by an equivalent linear stiffness using soil properties that are compatible with the soil strain levels associated with the design earthquake motion. The strain-compatible shear modulus, G, and the associated strain-compatible shear wave velocity, v_S, needed for the evaluation of equivalent linear stiffness shall be determined using the criteria in Chapter 19 or based on a site-specific study. The strain-compatible shear modulus, G, shall be varied over a range defined with an upper bound equal to $G(1 + C_{vs})$ and a lower bound equal to $G/(1 + C_{vs})$, where C_{vs} is the coefficient of variation which accounts for uncertainties in the SSI analysis and soil properties. The factor C_{vs} shall be taken as 1.0 unless smaller variations can be justified based on field measurements of dynamic soil properties or direct measurements of dynamic foundation stiffness. In no case shall the value of C_{vs} be taken as less than 0.5. The largest values of response shall be used in design.

12.13.4 Reduction of Foundation Overturning Overturning effects at the soil–foundation interface are permitted to be reduced by 25% for foundations of structures that satisfy both of the following conditions:

(a) The structure is designed in accordance with the equivalent lateral force analysis as set forth in Section 12.8, and
(b) The structure is not an inverted pendulum or cantilevered column type structure.

Overturning effects at the soil–foundation interface are permitted to be reduced by 10% for foundations of structures designed in accordance with the modal analysis requirements of Section 12.9.

@seismicisolation

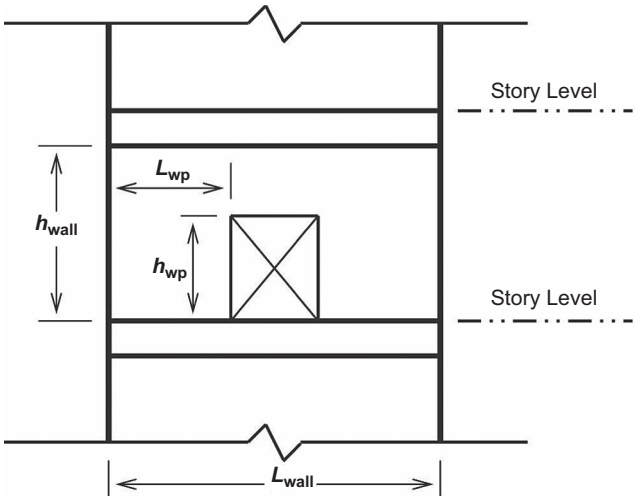

Figure 12.3-2. Shear wall and wall pier height-to-length ratio determination.

Note: h_{wall} = height of shear wall; h_{wp} = height of wall pier; L_{wall} = length of shear wall; L_{wp} = length of wall pier. Shear wall height-to-length ratio: h_{wall}/L_{wall}. Wall pier height-to-length ratio: h_{wp}/L_{wp}.

12.13.5 Strength Design for Foundation Geotechnical Capacity Where basic combinations for strength design listed in Section 2.3 are used, combinations that include earthquake loads, E, are permitted to include reduction of foundation overturning effects defined in Section 12.13.4. The following sections shall apply for determination of the applicable nominal strengths and resistance factors at the soil–foundation interface.

12.13.5.1 Nominal Strength The nominal foundation geotechnical capacity, Q_{ns}, shall be determined using any of the following methods:

1. Presumptive load-bearing values;
2. By a registered design professional based on geotechnical site investigations that include field and laboratory testing to determine soil classification and as-required active, passive, and at-rest soil strength parameters; or
3. By in situ testing of prototype foundations.

For structures that are supported on more than one foundation, the method used to determine the nominal strength of all foundations shall be the same. Nominal strength values are permitted to be based on either a limitation of maximum expected foundation deformation, or by the nominal strength that is associated with an anticipated failure mechanism.

12.13.5.1.1 Soil Strength Parameters For competent soils that do not undergo strength degradation under seismic loading, strength parameters for static loading conditions shall be used to compute nominal foundation geotechnical capacities for seismic design unless increased seismic strength values based on site conditions are provided by a registered design professional. For sensitive cohesive soils or saturated cohesionless soils, the potential for earthquake-induced strength degradation shall be considered. Nominal foundation geotechnical capacities for vertical, lateral, and rocking loading shall be determined using accepted foundation design procedures and principles of plastic analysis, and shall be best-estimate values using soil properties that are representative average values.

Total resistance to lateral loads is permitted to be determined by taking the sum of the values derived from lateral bearing pressure plus horizontal sliding resistance (from some combination of friction and cohesion).

1. Lateral sliding resistance from friction shall be limited to sand, silty sand, clayey sand, silty gravel, and clayey gravel soils (SW, SP, SM, SC, GM, and GC), and rock. Lateral sliding resistance from friction shall be calculated as the most unfavorable dead load factor multiplied by dead load, D, and multiplied by a coefficient of friction.
2. Lateral sliding resistance from cohesion shall be limited to clay, sandy clay, clayey silt, silt, and sandy silt (CL, ML, SC, and SM). Lateral sliding resistance from cohesion shall be calculated as the contact area multiplied by the cohesion.
3. Horizontal friction sliding resistance and cohesion sliding resistance shall be taken as zero for areas of foundations supported by piles.

Where presumptive load bearing values for supporting soils are used to determine nominal soil strengths, organic silt, organic clays, peat, or nonengineered fill shall not be assumed to have a presumptive load capacity.

12.13.5.2 Resistance Factors The resistance factors prescribed in this section shall be used for vertical, lateral, and rocking resistance of all foundation types. Nominal foundation geotechnical capacities, Q_{ns}, shall be multiplied by the resistance factor, φ, shown in Table 12.13-1. Alternatively, a vertical resistance factor, $\varphi = 0.80$, is permitted to be used when the nominal strength (upward or downward) is determined by in-situ testing of prototype foundations, based on a test program that is approved by the Authority Having Jurisdiction.

12.13.5.3 Acceptance Criteria For linear seismic analysis procedures in accordance with Sections 12.8 and 12.9, factored loads, including reductions permitted in Section 12.13.4, shall not exceed foundation design strengths, ϕQ_{ns}.

12.13.6 Allowable Stress Design for Foundation Geotechnical Capacity Where basic combinations for allowable stress design listed in Section 2.4 are used for design, combinations that include earthquake loads, E, are permitted to include reduction of foundation overturning effects defined in Section 12.13.4. Allowable foundation load capacities, Q_{as}, shall be determined using allowable stresses in geotechnical materials that have been determined by geotechnical investigations required by the Authority Having Jurisdiction.

12.13.7 Requirements for Structures Assigned to Seismic Design Category C In addition to the requirements of Section 11.8.2, the following foundation design requirements shall apply to structures assigned to Seismic Design Category C.

12.13.7.1 Pole-Type Structures Where construction using posts or poles as columns embedded in earth or embedded in concrete

Table 12.13-1. Resistance Factors for Strength Design of Soil–Foundation Interface.

Direction and Type of Resistance	Resistance Factor, φ
Vertical Resistance	
Compression (bearing) strength	0.45
Pile friction (either upward or downward)	0.45
Lateral Resistance	
Lateral bearing pressure	0.5
Sliding (by either friction or cohesion)	0.85

@seismicisolation

footings in the earth is used to resist lateral loads, the depth of embedment required for posts or poles to resist seismic forces shall be determined by means of the design criteria established in the foundation investigation report.

12.13.7.2 Foundation Ties Individual pile caps, drilled piers, or caissons shall be interconnected by ties. All ties shall have a design strength in tension or compression at least equal to a force equal to 10% of S_{DS} times the larger pile cap or column factored dead plus factored live load unless it is demonstrated that equivalent restraint will be provided by reinforced concrete beams within slabs on grade or reinforced concrete slabs on grade or confinement by competent rock, hard cohesive soils, very dense granular soils, or other approved means.

12.13.7.3 Pile Anchorage Requirements In addition to the requirements of ACI 318, anchorage of piles shall comply with this section. Where required for resistance to uplift forces, anchorage of steel pipe [round hollow structural steel (HSS) sections], concrete-filled steel pipe, or H piles to the pile cap shall be made by means other than concrete bond to the bare steel section.

EXCEPTION: Anchorage of concrete-filled steel pipe piles is permitted to be accomplished using deformed bars developed into the concrete portion of the pile.

12.13.8 Requirements for Structures Assigned to Seismic Design Categories D through F In addition to the requirements of Sections 11.8.2, 11.8.3 and 14.1.8, the following foundation design requirements shall apply to structures assigned to Seismic Design Category D, E, or F. Design and construction of concrete foundation elements shall conform to the requirements of ACI 318, Section 18.13, except as modified by the requirements of this section.

EXCEPTION: Detached one- and two-family dwellings of light-frame construction not exceeding two stories above grade plane need only comply with the requirements for Sections 11.8.2, 11.8.3 (items 2 through 4), 12.13.2, and 12.13.7.

12.13.8.1 Pole-Type Structures Where construction using posts or poles as columns embedded in earth or embedded in concrete footings in the earth is used to resist lateral loads, the depth of embedment required for posts or poles to resist seismic forces shall be determined by means of the design criteria established in the foundation investigation report.

12.13.8.2 Foundation Ties Individual pile caps, drilled piers, or caissons shall be interconnected by ties. In addition, individual spread footings founded on soil defined in Chapter 20 as Site Class E or F shall be interconnected by ties. All ties shall have a design strength in tension or compression at least equal to a force equal to 10% of S_{DS} times the larger pile cap or column factored dead plus factored live load unless it is demonstrated that equivalent restraint is provided by reinforced concrete beams within slabs on grade or reinforced concrete slabs on grade or confinement by competent rock, hard cohesive soils, very dense granular soils, or other approved means.

12.13.8.3 General Pile Design Requirement Piling shall be designed and constructed to withstand deformations from earthquake ground motions and structure response. Deformations shall include both free-field soil strains (without the structure) and deformations induced by lateral pile resistance to structure seismic forces, all as modified by soil–pile interaction.

12.13.8.4 Batter Piles Batter piles and their connections shall be capable of resisting forces and moments from the load combinations including overstrength from Chapter 2 or Section 12.14.3.2.3. Where vertical and batter piles act jointly to resist foundation forces as a group, these forces shall be distributed to the individual piles in accordance with their relative horizontal and vertical rigidities and the geometric distribution of the piles within the group.

12.13.8.5 Pile Anchorage Requirements In addition to the requirements of Section 12.13.7.3, anchorage of piles shall comply with this section. Design of anchorage of piles into the pile cap shall consider the combined effect of axial forces because of uplift and bending moments caused by fixity to the pile cap. For piles required to resist uplift forces or provide rotational restraint, anchorage into the pile cap shall comply with the following:

1. In the case of uplift, the anchorage shall be capable of developing the least of the nominal tensile strength of the longitudinal reinforcement in a concrete pile, the nominal tensile strength of a steel pile, and 1.3 times the pile pullout resistance, or shall be designed to resist the axial tension force resulting from the seismic load effects including overstrength of Section 12.4.3 or 12.14.3.2. The pile pullout resistance shall be taken as the ultimate frictional or adhesive force that can be developed between the soil and the pile plus the pile weight.
2. In the case of rotational restraint, the anchorage shall be designed to resist the axial and shear forces and moments resulting from the seismic load effects including overstrength of Section 12.4.3 or 12.14.3.2 or shall be capable of developing the full axial, bending, and shear nominal strength of the pile.

12.13.8.6 Splices of Pile Segments Splices of pile segments shall develop the nominal strength of the pile section.

EXCEPTION: Splices designed to resist the axial and shear forces and moments from the seismic load effects including overstrength of Section 12.4.3 or 12.14.3.2.

12.13.8.7 Pile–Soil Interaction Pile moments, shears, and lateral deflections used for design shall be established considering the interaction of the pile and soil. Where the ratio of the depth of embedment of the pile to the pile diameter or width is less than or equal to 6, the pile is permitted to be assumed to be flexurally rigid with respect to the soil.

12.13.8.8 Pile Group Effects Pile group effects from soil on lateral pile nominal strength shall be included where pile center-to-center spacing in the direction of lateral force is less than eight pile diameters or widths. Pile group effects on vertical nominal strength shall be included where pile center-to-center spacing is less than three pile diameters or widths.

12.13.9 Requirements for Foundations Subject to Seismically-Induced Soil Displacement or Strength Loss Where the geotechnical investigation report required in Section 11.8 identifies the potential for liquefaction, seismically-induced permanent ground displacement, or soil strength loss in MCE_G earthquake motions, structures shall be designed to accommodate the effects in accordance with the requirements of Sections 12.13.9.1 through 12.13.9.3. Such structures shall also be designed to resist the seismic load effects of Section 12.4, presuming these effects do not occur.

EXCEPTION: Structures on shallow foundations need not be designed for the requirements of this section where the geotechnical investigation report indicates a negligible

@seismicisolation

potential for the occurrence of permanent horizontal ground displacement, no bearing capacity loss, no lateral resistance loss, and differential settlements of site soils or improved site soils do not exceed one-fourth of the differential settlement threshold specified in Table 12.3-3.

Where the geotechnical investigation report indicates the potential for flow failure or seismically-induced long runout landslides, the provisions of Section 12.13.9 are not applicable and the condition shall be mitigated.

12.13.9.1 Foundation Design Foundations shall be designed to support gravity and design earthquake loads, as indicated in the basic load combinations of Section 12.4, using the reduced soil bearing capacity, as indicated in the geotechnical investigation report, considering the effects of liquefaction, seismically-induced permanent ground displacement, and soil strength loss caused by MCE_G earthquake motions. It shall be permitted to include the mitigating effects of any planned improvements for the site.

12.13.9.2 Shallow Foundations Building structures shall be permitted to be supported on shallow foundations provided that the foundations are designed and detailed in accordance with Section 12.13.9.2.1 and the conditions provided in items (a) and (b) of Section 12.13.9.2 are met.

(a) The geotechnical investigation report indicates that seismically-induced permanent horizontal ground displacement does not exceed the value in Table 12.13-2.
(b) The geotechnical investigation report indicates that the differential settlement over a defined length, L, does not exceed the differential settlement threshold specified in Table 12.13-3.

EXCEPTION: It is permitted to exceed the differential settlement threshold specified in Table 12.13-3 for shallow foundations, provided the foundation and superstructure are designed to accommodate seismically-induced differential settlements without loss of the ability to support gravity loads in addition to the requirements of Section 12.13.9.2.1. For structures assigned to Risk Category II or III, residual strength of members and connections shall not be less than 67% of the undamaged nominal strength, considering the nonlinear behavior of the structure or, alternatively, demands on all members and connections shall not exceed the element's nominal strength when subjected to differential settlements. For structures assigned to Risk Category IV, demands on all members and connections shall not exceed the element's nominal strength when subjected to differential settlements.

12.13.9.2.1 Shallow Foundation Design Shallow foundations shall satisfy the design and detailing requirements of Sections 12.13.9.2.1.1 or 12.13.9.2.1.2 as required.

12.13.9.2.1.1 Foundation Ties Individual footings shall be interconnected by ties in accordance with Section 12.13.8.2 and the additional requirements of this section. Reinforced concrete sections shall be detailed in accordance with Sections 18.13.4 of ACI 318. Where the geotechnical investigation report indicates that seismically-induced permanent horizontal ground displacement exceeding 3 in. (76.2 mm) will occur in MCE_G earthquake motions, both of the following requirements shall be met.

1. Ties between individual footings on the same column or wall line shall, in lieu of the force requirements of Section 12.13.8.2, have a design strength in tension and compression at least equal to the design tie force, F_{tie}, as indicated in Equation (12.13-1). These effects shall be combined with the load effects from design earthquake lateral loads.

$$F_{\text{tie}} = 0.5\mu P_u \qquad (12.13\text{-}1)$$

where μ is the coefficient of friction between the bottom of the footing and the soil, as indicated in the geotechnical report, or taken as 0.5 in the absence of other information; and P_u is the total of the supported gravity loads of all footings along the same column or wall line, determined in accordance with load combination 6 in Section 2.3.6.

2. Individual footings shall be integral with or connected to a reinforced concrete slab-on-ground, at least 5 in. (127.0 cm) thick and reinforced in each horizontal direction with a minimum reinforcing ratio of 0.0025. Alternately, individual footings shall be integral with or connected to a posttensioned concrete slab on ground designed according to PTI DC10.5 with a minimum effective compression after losses of 100 psi (690 kPa). For sites with expansive soils, movements from both expansive soils and seismically-induced permanent ground displacement need not be considered concurrently. For purposes of this section, concrete slab on ground need not satisfy Section 18.6.4 of ACI 318.

EXCEPTION: A system of diagonal reinforced concrete ties is permitted to be used, if the system of ties provides equivalent

Table 12.13-2. Upper Limit on Permanent Horizontal Ground Displacement for Shallow Foundations.

Risk Category	I or II	III	IV
Limit, in. (mm)	18 (455)	12 (305)	4 (100)

Table 12.13-3. Differential Settlement Threshold.

Structure Type	Risk Category		
	I or II	III	IV

Other multistory structures	0.010L	0.006L	0.002L

@seismicisolation

lateral shear strength and stiffness to a slab on ground as defined above.

12.13.9.2.1.2 Mat Foundations Mat foundations shall be designed to accommodate the expected vertical differential settlements indicated in the geotechnical investigation report, considering any increased loads induced by differential settlements of adjacent columns. The flexural demands caused by seismically-induced differential settlement need not be considered if the mat is detailed in accordance with the requirements of Section 18.13.3.1 of ACI 318. Mat foundations shall have longitudinal reinforcement in both directions at the top and bottom.

12.13.9.3 Deep Foundations Deep foundations shall be designed to support vertical loads as indicated in the basic load combinations of Section 12.4, in combination with the moments and shears caused by lateral deformation of deep foundation elements in response to lateral inertial loads. Axial capacity of the deep foundation and lateral resistance of the soil shall be reduced to account for the effects of liquefaction and reduced soil strength. Deep foundations shall satisfy the design and detailing requirements of Sections 12.13.9.3.1 through 12.13.9.3.5.

12.13.9.3.1 Downdrag Design of piles shall incorporate the effects of downdrag caused by seismically-induced settlement. For geotechnical design, the downdrag load shall be determined as the downward skin friction on the pile within and above the settling zone(s). The net geotechnical ultimate capacity of the pile shall be the ultimate geotechnical capacity of the pile below the settling zone(s) reduced by the downdrag load. For structural design, the downdrag load induced by seismic settlement shall be treated and factored as a seismic load, though it need not be considered concurrently with axial loads resulting from inertial response of the structure, determined according to Section 12.4.

EXCEPTION: In lieu of the procedure defined in this section, rational analysis is permitted to be used to determine the downdrag load and the net geotechnical ultimate capacity of the pile if the seismically-induced foundation differential settlement is indicated in the geotechnical investigation report and one of the following requirements is met:

1. The seismically-induced foundation differential settlement does not exceed one-fourth of the differential settlement threshold in Table 12.13-3.
2. The seismically-induced foundation differential settlement does not exceed the differential settlement threshold in Table 12.13-3 and does not exceed $0.0075L$; foundation ties comply with the additional detailing requirements of Section 12.13.9.2.1.1; and mat foundations comply with the requirements of Section 12.13.9.2.1.2.
3. The seismically-induced foundation differential settlement complies with the design requirements of Section 12.13.9.2(b); foundation ties comply with the additional detailing requirements of Section 12.13.9.2.1.1; and mat foundations comply with the requirements of Section 12.13.9.2.1.2.

12.13.9.3.2 Lateral Resistance Passive pressure and friction mobilized against walls, pile caps, and grade beams, when reduced for the effects of liquefaction and seismically-induced reduction in soil strength, shall be permitted to resist lateral inertial loads in combination with piles. Resistance provided by the combination of piles, passive pressure, and friction shall be determined based on compatible lateral deformations.

12.13.9.3.3 Concrete Deep Foundation Detailing Concrete piles, including cast-in-place and precast piles, shall be detailed to comply with Section 18.13.5.5 of ACI 318 from the top of the pile to a depth exceeding that of the deepest liquefiable soil by at least 7 times the member cross-sectional dimension.

12.13.9.3.4 Permanent Horizontal Ground Displacement Where the geotechnical investigation report indicates a potential for seismically-induced permanent horizontal ground displacement will occur in the event of MCE_G earthquake motions, pile design shall be based on a detailed analysis incorporating the expected lateral deformation, the depths over which the deformation is expected to occur, and the nonlinear behavior of the piles. Where nonlinear behavior of piles occurs caused by seismically-induced permanent horizontal ground displacement, the pile deformations shall not result in loss of the pile's ability to carry gravity loads, nor shall the deteriorated pile's lateral strength be less than 67% of the undamaged nominal strength. In addition, the following requirements shall be satisfied:

1. Structural steel H-piles shall satisfy the width-thickness limits for highly ductile H-pile members in ANSI/AISC 341.
2. Unfilled structural steel pipe piles shall satisfy the width-thickness limits for highly ductile round hollow structural steel (HSS) elements in ANSI/AISC 341.
3. Concrete piles shall be detailed to comply with Section 18.13.5.5 of ACI 318 from the top of the pile to a depth exceeding that of the deepest layer of soil prone to seismically-induced permanent horizontal ground displacement by at least 7 times the pile diameter. Nominal shear strength shall exceed the maximum forces that can be generated because of pile deformations determined in the detailed analysis.

12.13.9.3.5 Foundation Ties Individual pile caps shall be interconnected by ties in accordance with Section 12.13.8.2. Where the geotechnical investigation report indicates seismically-induced permanent horizontal ground displacement, the design forces for ties shall include the additional pressures applied to foundation elements because of the lateral displacement in accordance with the recommendations of the geotechnical investigation report. These effects shall be combined with the load effects from design earthquake lateral loads.

12.14 SIMPLIFIED ALTERNATIVE STRUCTURAL DESIGN CRITERIA FOR SIMPLE BEARING WALL OR BUILDING FRAME SYSTEMS

12.14.1 General

12.14.1.1 Simplified Design Procedure The procedures of this section are permitted to be used in lieu of other analytical procedures in Chapter 12 for the analysis and design of simple buildings with bearing wall or building frame systems, subject to all of the limitations listed in this section. Where these procedures are used, the Seismic Design Category shall be determined from Table 11.6-1 using the value of S_{DS} from Section 12.14.8.1, except that where S_1 is greater than or equal to 0.75, the Seismic Design Category shall be E. The simplified design procedure is permitted to be used if the following limitations are met.

1. The structure shall qualify for Risk Category I or II in accordance with Table 1.5-1.

@seismicisolation

2. The site class, defined in Chapter 20, shall not be Site Class E or F.
3. The structure shall not exceed three stories above grade plane.
4. The seismic force-resisting system shall be either a bearing wall system or a building frame system, as indicated in Table 12.14-1.
5. The structure shall have at least two lines of lateral resistance in each of two major axis directions. At least one line of resistance shall be provided on each side of the center of weight in each direction.
6. The center of weight in each story shall be located not further from the geometric centroid of the diaphragm than 10% of the length of the diaphragm parallel to the eccentricity.
7. For structures with cast-in-place concrete diaphragms, overhangs beyond the outside line of shear walls or braced frames shall satisfy the following:

$$a \le d/3 \qquad (12.14\text{-}1)$$

where a is the distance perpendicular to the forces being considered from the extreme edge of the diaphragm to the line of vertical resistance closest to that edge, and d is the depth of the diaphragm parallel to the forces being considered at the line of vertical resistance closest to the edge.

All other diaphragm overhangs beyond the outside line of shear walls or braced frames shall satisfy

$$a \le d/5 \qquad (12.14\text{-}2)$$

8. For buildings with a diaphragm that is not flexible, the forces shall be apportioned to the vertical elements as if the diaphragm were flexible. The following additional requirements shall be satisfied:
   (a) For structures with two lines of resistance in a given direction, the distance between the two lines is at least 50% of the length of the diaphragm perpendicular to the lines; and
   (b) For structures with more than two lines of resistance in a given direction, the distance between the two most extreme lines of resistance in that direction is at least 60% of the length of the diaphragm perpendicular to the lines.

   Where two or more lines of resistance are closer together than one-half the horizontal length of the longer of the walls or braced frames, it shall be permitted to replace those lines by a single line at the centroid of the group for the initial distribution of forces, and the resultant force to the group shall then be distributed to the members of the group based on their relative stiffnesses.
9. Lines of resistance of the seismic force-resisting system shall be oriented at angles of no more than 15 degrees from alignment with the major orthogonal horizontal axes of the building.
10. The simplified design procedure shall be used for each major orthogonal horizontal axis direction of the building.
11. System irregularities caused by in-plane or out-of-plane offsets of lateral force-resisting elements shall not be permitted.

    EXCEPTION: Out-of-plane and in-plane offsets of shear walls are permitted in two-story buildings of light-frame construction provided that the framing supporting the upper wall is designed for seismic force effects from overturning of the wall amplified by a factor of 2.5.
12. The story lateral strength of any story shall not be less than 80% of that in the story above. The story lateral strength is the total lateral strength of all seismic force-resisting system elements resisting the story shear for the direction under consideration.

12.14.1.2 Reference Documents The reference documents listed in Chapter 23 shall be used as indicated in Section 12.14.

12.14.1.3 Definitions The definitions listed in Section 11.2 shall be used in addition to the following:

PRINCIPAL ORTHOGONAL HORIZONTAL DIRECTIONS: The orthogonal directions that overlay the majority of lateral force-resisting elements.

12.14.1.4 Notation

D = Effect of dead load
E = Effect of horizontal and vertical earthquake-induced forces
F_a = Acceleration-based site coefficient, see Section 12.14.8.1
F_i = Portion of the seismic base shear, V, induced at level i
F_p = Seismic design force applicable to a particular structural component
F_x = See Section 12.14.8.2
h_i = Height above the base to level i
h_x = Height above the base to level x
Level i = Building level referred to by the subscript i; $i = 1$ designates the first level above the base
Level n = Level that is uppermost in the main portion of the building
Level x = See Level i
Q_E = Effect of horizontal seismic forces
R = Response modification coefficient as given in Table 12.14-1
S_{DS} = See Section 12.14.8.1
S_S = See Section 11.4.1
S_1 = See Section 11.4.1
V = Total design shear at the base of the structure in the direction of interest, as determined using the procedure of Section 12.14.8.1
V_x = Seismic design shear in story x; see Section 12.14.8.3
W = See Section 12.14.8.1
W_c = Weight of wall
w_i = Portion of the effective seismic weight, W, located at or assigned to level i
W_p = Weight of structural component
w_x = See Section 12.14.8.2

12.14.2 Design Basis The structure shall include complete lateral and vertical force-resisting systems with adequate strength to resist the design seismic forces, specified in this section, in combination with other loads. Design seismic forces shall be distributed to the various elements of the structure and their connections using a linear elastic analysis in accordance with the procedures of Section 12.14.8. The members of the seismic force-resisting system and their connections shall be detailed to conform with the applicable requirements for the selected structural system as indicated in Section 12.14.4.1. A continuous load path, or paths, with adequate strength and stiffness shall be provided to transfer all forces from the point of application to the final point of resistance. The foundation shall be designed to accommodate the forces developed.

12.14.3 Seismic Load Effects All members of the structure, including those not part of the seismic force-resisting system, shall be designed using the seismic load effects of

Table 12.14-1 *(Continued)*.

Seismic Force-Resisting System	ASCE 7 Section Where Detailing Requirements Are Specified	Response Modification Coefficient, R[a]	Limitations[b]		
			Seismic Design Category		
			B	C	D, E
24. Light-frame walls with shear panels of all other materials	14.1 and 14.5	2½	P	P	NP[d]
25. Steel buckling-restrained braced frames	14.1	8	P	P	P
26. Steel special plate shear walls	14.1	7	P	P	P

[a] Response modification coefficient, R, for use throughout the standard.
[b] P = permitted; NP = not permitted.
[c] Light-frame walls with shear panels of all other materials are not permitted in Seismic Design Category E.
[d] Light-frame walls with shear panels of all other materials are permitted up to 35 ft (10.6 m) in structural height, h_n, in Seismic Design Category D and are not permitted in Seismic Design Category E.

Section 12.14.3 unless otherwise exempted by this standard. Seismic load effects are the axial, shear, and flexural member forces resulting from application of horizontal and vertical seismic forces as set forth in Section 12.14.3.1. Where required, seismic load effects shall include overstrength, as set forth in Section 12.14.3.2.

12.14.3.1 Seismic Load Effect The seismic load effect, E, includes effects of both horizontal and vertical ground motions as shown in Eq. (12.14-3) and Eq. (12.14-4).

$$E = E_h + E_v \tag{12.14-3}$$

$$E = E_h - E_v \tag{12.14-4}$$

where E_h is the effect of horizontal seismic forces as defined in Section 12.14.3.1.1, and E_v is the effect of vertical seismic forces as defined in Section 12.14.3.1.2.

E_h and E_v shall be used in load combinations 6 and 7 in Section 2.3.6 and in load combinations 8, 9, and 10 in Section 2.4.5.

12.14.3.1.1 Horizontal Seismic Load Effect The horizontal seismic load effect, E_h, shall be determined in accordance with Equation (12.14-5) as follows:

$$E_h = Q_E \tag{12.14-5}$$

where Q_E is the effects of horizontal seismic forces from V or F_p as specified in Sections 12.14.7.5, 12.14.8.1, and 13.3.1.

12.14.3.1.2 Vertical Seismic Load Effect The vertical seismic load effect, E_v, shall be determined in accordance with Equation (12.14-6) as follows:

$$E_v = 0.2 S_{DS} D \tag{12.14-6}$$

where S_{DS} is the design spectral response acceleration parameter at short periods obtained from Section 11.4.5, and D is the effect of dead load.

EXCEPTION: The vertical seismic load effect, E_v, is permitted to be taken as zero for either of the following conditions:

1. In Equations (12.14-3), (12.14-4), (12.14-7), and (12.14-8) where S_{DS} is equal to or less than 0.125; and
2. In Equation (12.14-4) where determining demands on the soil–structure interface of foundations.

12.14.3.2 Seismic Load Effect Including Overstrength The seismic load effect including overstrength, E_m includes effects of both horizontal and vertical ground motions as shown in Eq. (12.14-7) and Eq. (12.14-8). Where required, the seismic load effects, including overstrength, shall be determined in accordance with the following.

$$E_m = E_{mh} + E_v \tag{12.14-7}$$

$$E_m = E_{mh} - E_v \tag{12.14-8}$$

where

E_m = Seismic load effect including overstrength
E_{mh} = The effect of horizontal seismic forces, including overstrength, as defined in Section 12.14.3.2.1 or 12.14.3.2.2; and
E_v = The vertical seismic load effect as defined in Section 12.14.3.1.2.

E_{mh} and E_v shall be used in load combinations 6 and 7 in Section 2.3.6 and in load combinations 8, 9, and 10 in Section 2.4.5.

12.14.3.2.1 Horizontal Seismic Load Effect with a 2.5 Overstrength The effect of horizontal seismic forces, including overstrength, E_{mh}, shall be determined in accordance with Equation (12.14-9) as follows:

$$E_{mh} = 2.5 Q_E \tag{12.14-9}$$

where Q_E is the effects of horizontal seismic forces from V or F_p as specified in Sections 12.14.7.5, 12.14.8.1, and 13.3.1.

E_{mh} need not be taken as larger than E_{cl}, where E_{cl} = The capacity-limited horizontal seismic load effect as defined in Section 11.3.

12.14.3.2.2 Capacity-Limited Horizontal Seismic Load Effect Where capacity-limited design is required by the material reference document, the seismic load effect including overstrength shall be calculated with the capacity-limited horizontal seismic load effect, E_{cl}, substituted for E_{mh} in the load combinations of Section 2.3.6 and Section 2.4.5.

12.14.4 Seismic Force-Resisting System

12.14.4.1 Selection and Limitations The basic lateral and vertical seismic force-resisting system shall conform to one of

@seismicisolation

the types indicated in Table 12.14-1 and shall conform to all of the detailing requirements referenced in the table. The appropriate response modification coefficient, R, indicated in Table 12.14-1 shall be used in determining the base shear and element design forces as set forth in the seismic requirements of this standard.

Special framing and detailing requirements are indicated in Section 12.14.7 and in Sections 14.1, 14.2, 14.3, 14.4, and 14.5 for structures assigned to the various Seismic Design Categories.

12.14.4.2 Combinations of Framing Systems

12.14.4.2.1 Horizontal Combinations Different seismic force-resisting systems are permitted to be used in each of the two principal orthogonal building directions. Where a combination of different structural systems is used to resist lateral forces in the same direction, the value of R used for design in that direction shall not be greater than the least value of R for any of the systems used in that direction.

EXCEPTION: For buildings of light-frame construction or buildings that have flexible diaphragms and that are two stories or fewer above grade plane, resisting elements are permitted to be designed using the least value of R of the different seismic force-resisting systems found in each independent line of framing. The value of R used for design of diaphragms in such structures shall not be greater than the least value for any of the systems used in that same direction.

12.14.4.2.2 Vertical Combinations Different seismic force-resisting systems are permitted to be used in different stories. The value of R used in a given direction shall not be greater than the least value of any of the systems used in that direction.

12.14.4.2.3 Combination Framing Detailing Requirements The detailing requirements of Section 12.14.7 required by the higher response modification coefficient, R, shall be used for structural members common to systems that have different response modification coefficients.

12.14.5 Diaphragm Flexibility Diaphragms constructed of steel decking (untopped), wood structural panels, or similar panelized construction techniques are permitted to be considered flexible.

12.14.6 Application of Loading The effects of the combination of loads shall be considered as prescribed in Section 12.14.3. The design seismic forces are permitted to be applied separately in each orthogonal direction, and the combination of effects from the two directions need not be considered. Reversal of load shall be considered.

12.14.7 Design and Detailing Requirements The design and detailing of the members of the seismic force-resisting system shall comply with the requirements of this section. The foundation shall be designed to resist the forces developed and accommodate the movements imparted to the structure by the design ground motions. The dynamic nature of the forces, the expected ground motion, the design basis for strength and energy dissipation capacity of the structure, and the dynamic properties of the soil shall be included in the determination of the foundation design criteria. The design and construction of foundations shall comply with Section 12.13. Structural elements including foundation elements shall conform to the material design and detailing requirements set forth in Chapter 14.

12.14.7.1 Connections All parts of the structure between separation joints shall be interconnected, and the connection shall be capable of transmitting the seismic force, F_p, induced by the parts being connected. Any smaller portion of the structure shall be tied to the remainder of the structure with elements that have a strength of 0.20 times the short-period design spectral response acceleration coefficient, S_{DS}, times the weight of the smaller portion or 5% of the portion's weight, whichever is greater.

A positive connection for resisting a horizontal force acting parallel to the member shall be provided for each beam, girder, or truss, either directly to its supporting elements or to slabs designed to act as diaphragms. Where the connection is through a diaphragm, then the member's supporting element must also be connected to the diaphragm. The connection shall have minimum design strength of 5% of the dead plus live load reaction.

12.14.7.2 Openings or Reentrant Building Corners Except where otherwise specifically provided for in this standard, openings in shear walls, diaphragms, or other plate-type elements shall be provided with reinforcement at the edges of the openings or reentrant corners designed to transfer the stresses into the structure. The edge reinforcement shall extend into the body of the wall or diaphragm a distance sufficient to develop the force in the reinforcement.

EXCEPTION: Shear walls of wood structural panels are permitted where designed in accordance with AWC SDPWS for perforated shear walls or ANSI/AISI S400 for Type II shear walls.

12.14.7.3 Collector Elements Collector elements shall be provided with adequate strength to transfer the seismic forces originating in other portions of the structure to the element providing the resistance to those forces (Figure 12.10-1). Collector elements, splices, and their connections to resisting elements shall be designed to resist the forces defined in Section 12.14.3.2.

EXCEPTION: In structures, or portions thereof, braced entirely by light-frame shear walls, collector elements, splices, and connections to resisting elements are permitted to be designed to resist forces in accordance with Section 12.14.7.4.

12.14.7.4 Diaphragms Floor and roof diaphragms shall be designed to resist the design seismic forces at each level, F_x, calculated in accordance with Section 12.14.8.2. Where the diaphragm is required to transfer design seismic forces from the vertical-resisting elements above the diaphragm to other vertical-resisting elements below the diaphragm because of changes in relative lateral stiffness in the vertical elements, the transferred portion of the seismic shear force at that level, V_x, shall be added to the diaphragm design force. Diaphragms shall provide for both the shear and bending stresses resulting from these forces. Diaphragms shall have ties or struts to distribute the wall anchorage forces into the diaphragm. Diaphragm connections shall be positive, mechanical, or welded type connections.

12.14.7.5 Anchorage of Structural Walls Structural walls shall be anchored to all floors, roofs, and members that provide out-of-plane lateral support for the wall or that are supported by the wall. The anchorage shall provide a positive direct connection between the wall and floor, roof, or supporting member with the strength to resist the out-of-plane force given by Equation (12.14-10):

$$F_p = 0.4 k_a S_{DS} W_p \tag{12.14-10}$$

where

$$k_a = 1.0 + \frac{L_f}{100} \tag{12.14-11}$$

and k_a need not be taken as larger than 2.0;

@seismicisolation

L_f = Span, in feet, of a flexible diaphragm that provides the lateral support for the wall (the span is measured between vertical elements that provide lateral support to the diaphragm in the direction considered—use zero for rigid diaphragms);
F_p = Design force in the individual anchors;
k_a = Amplification factor for diaphragm flexibility;
S_{DS} = Design spectral response acceleration at short periods per Section 12.14.8.1;
W_p = Weight of the wall tributary to the anchor; and
F_p = Shall not be taken as less than the larger of $0.2k_aW_p$ and 5 lb/ft^2 (0.24 kN/m^2) times the area of the wall tributary to the anchor.

12.14.7.5.1 Transfer of Anchorage Forces into Diaphragms Diaphragms shall be provided with continuous ties or struts between diaphragm chords to distribute these anchorage forces into the diaphragms. Added chords are permitted to be used to form subdiaphragms to transmit the anchorage forces to the main continuous crossties. The maximum length-to-width ratio of the structural subdiaphragm shall be 2.5 to 1. Connections and anchorages capable of resisting the prescribed forces shall be provided between the diaphragm and the attached components. Connections shall extend into the diaphragm a sufficient distance to develop the force transferred into the diaphragm.

12.14.7.5.2 Wood Diaphragms The anchorage of concrete or masonry structural walls to wood diaphragms shall be in accordance with AWC SDPWS 4.1.5.1 and this section. Continuous ties required by this section shall be in addition to the diaphragm sheathing. Anchorage shall not be accomplished by use of toenails or nails subject to withdrawal, nor shall wood ledgers or framing be used in cross-grain bending or cross-grain tension. The diaphragm sheathing shall not be considered effective as providing the ties or struts required by this section.

12.14.7.5.3 Metal Deck Diaphragms In metal deck diaphragms, the metal deck shall not be used as the continuous ties required by this section in the direction perpendicular to the deck span.

12.14.7.5.4 Embedded Straps Diaphragm to wall anchorage using embedded straps shall be attached to or hooked around the reinforcing steel or otherwise terminated so as to effectively transfer forces to the reinforcing steel.

12.14.7.6 Bearing Walls and Shear Walls Exterior and interior bearing walls and shear walls and their anchorage shall be designed for a force equal to 40% of the short-period design spectral response acceleration, S_{DS}, times the weight of wall, W_c, normal to the surface, with a minimum force of 10% of the weight of the wall. Interconnection of wall elements and connections to supporting framing systems shall have sufficient ductility, rotational capacity, or strength to resist shrinkage, thermal changes, and differential foundation settlement where combined with seismic forces.

12.14.7.7 Anchorage of Nonstructural Systems Where required by Chapter 13, all portions or components of the structure shall be anchored for the seismic force, F_p, prescribed therein.

12.14.8 Simplified Lateral Force Analysis Procedure An equivalent lateral force analysis shall consist of the application of equivalent static lateral forces to a linear mathematical model of the structure. The lateral forces applied in each direction shall sum to a total seismic base shear given by Section 12.14.8.1 and shall be distributed vertically in accordance with Section 12.14.8.2. For purposes of analysis, the structure shall be considered fixed at the base.

12.14.8.1 Seismic Base Shear The seismic base shear, V, in a given direction shall be determined in accordance with Equation (12.14-12):

$$V = \frac{FS_{DS}}{R} W \tag{12.14-12}$$

where $S_{DS} = \frac{2}{3} F_a S_s$, where F_a is permitted to be taken as 1.0 for rock sites, 1.4 for soil sites, or determined in accordance with Section 11.4.4. For the purpose of this section, sites are permitted to be considered to be rock if there is no more than 10 ft (3 m) of soil between the rock surface and the bottom of spread footing or mat foundation. In calculating S_{DS}, S_s shall be in accordance with Section 11.4.4 but need not be taken as larger than 1.5;

F = 1.0 for buildings that are one story above grade plane, 1.1 for buildings that are two stories above grade plane, and 1.2 for buildings that are three stories above grade plane;
R = Response modification factor from Table 12.14-1; and
W = Effective seismic weight of the structure that includes the dead load, as defined in Section 3.1, above grade plane and other loads above grade plane as listed in the following text:

1. In areas used for storage, a minimum of 25% of the floor live load shall be included.
   EXCEPTIONS:
   (a) Where the inclusion of storage loads adds no more than 5% to the effective seismic weight at that level, it need not be included in the effective seismic weight.
   (b) Floor live load in public garages and open parking structures need not be included.
2. Where provision for partitions is required by Section 4.3.2 in the floor load design, the actual partition weight, or a minimum weight of 10 lb/ft^2 (0.48 kN/m^2) of floor area, whichever is greater.
3. Total operating weight of permanent equipment.
4. Where the flat roof snow load, P_f, exceeds 30 lb/ft^2 (1.44 kN/m^2), 20% of the uniform design snow load, regardless of actual roof slope.
5. Weight of landscaping and other materials at roof gardens and similar areas.

12.14.8.2 Vertical Distribution The forces at each level shall be calculated using the following equation:

$$F_x = \frac{w_x}{W} V \tag{12.14-13}$$

where w_x is the portion of the effective seismic weight of the structure, W, at level x.

12.14.8.3 Horizontal Shear Distribution The seismic design story shear in any story, V_x [kip (kN)], shall be determined from the following equation:

$$V_x = \sum_{1=x}^{n} F_i \tag{12.14-14}$$

where F_i is the the portion of the seismic base shear, V [kip (kN)], induced at level i.

@seismicisolation

12.14.8.3.1 Flexible Diaphragm Structures The seismic design story shear in stories of structures with flexible diaphragms, as defined in Section 12.14.5, shall be distributed to the vertical elements of the seismic force-resisting system using tributary area rules. Two-dimensional analysis is permitted where diaphragms are flexible.

12.14.8.3.2 Structures with Diaphragms That Are Not Flexible For structures with diaphragms that are not flexible, as defined in Section 12.14.5, the seismic design story shear, V_x [kip (kN)], shall be distributed to the various vertical elements of the seismic force-resisting system in the story under consideration based on the relative lateral stiffnesses of the vertical elements and the diaphragm.

12.14.8.3.2.1 Torsion The design of structures with diaphragms that are not flexible shall include the torsional moment, M_t [kip-ft (kN-m)], resulting from eccentricity between the locations of center of mass and the center of rigidity.

12.14.8.4 Overturning The structure shall be designed to resist overturning effects caused by the seismic forces determined in Section 12.14.8.2. The foundations of structures shall be designed for not less than 75% of the foundation overturning design moment, M_f [kip-ft (kN-m)], at the foundation–soil interface.

12.14.8.5 Drift Limits and Building Separation Structural drift need not be calculated. Where a drift value is needed for use in material standards, to determine structural separations between buildings or from property lines, for design of cladding, or for other design requirements, it shall be taken as 1% of structural height, h_n, unless computed to be less. Each portion of the structure shall be designed to act as an integral unit in resisting seismic forces unless it is separated structurally by a distance sufficient to avoid damaging contact under the total deflection.

12.15 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

See Chapter 23 for the list of consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

@seismicisolation
@seismicisolation

CHAPTER 13
SEISMIC DESIGN REQUIREMENTS FOR NONSTRUCTURAL COMPONENTS

13.1 GENERAL

13.1.1 Scope This chapter establishes minimum design criteria for nonstructural components, including their supports and attachments.

Nonstructural components include

1. Components that are in or supported by a structure,
2. Components that are outside of a structure (except for nonbuilding structures within the scope of Chapter 15) and are permanently connected to the mechanical or electrical systems, or
3. Components that are part of the egress system of a structure.

Where the weight of a nonstructural component is greater than or equal to 20% of the combined effective seismic weight, W, of the nonstructural component and the supporting structure as defined in Section 12.7.2, the component shall be designed in accordance with Section 13.2.9.

13.1.2 Seismic Design Category For the purposes of this chapter, nonstructural components shall be assigned to the same seismic design category as

1. The structure that they occupy or are supported by, or
2. The structure to which they are permanently connected by mechanical or electrical systems, or
3. For parts of an egress system, the structure it serves.

If more than one of these criteria is applicable, the highest seismic design category shall be used.

13.1.3 Component Importance Factor All components shall be assigned a component Importance Factor as indicated in this section. The component Importance Factor, I_p, shall be taken as 1.5 if any of the following conditions apply:

1. The component is required to function for life-safety purposes after an earthquake, including fire protection sprinkler systems and egress stairways.
2. The component conveys, supports, or otherwise contains toxic, highly toxic, or explosive substances where the quantity of the material exceeds a threshold quantity established by the Authority Having Jurisdiction and is sufficient to pose a threat to the public if released.
3. The component is in or supported by a Risk Category IV structure or permanently connected by mechanical or electrical systems to a Risk Category IV structure, and the component is required for the continued operation of a structure designated an Essential Facility, or its failure would impair the continued operation of a structure designated an Essential Facility.
4. The component conveys, supports, or otherwise contains hazardous substances and is attached to a structure or portion thereof classified by the Authority Having Jurisdiction as a hazardous occupancy.

All other components shall be assigned a component Importance Factor, I_p, equal to 1.0.

13.1.4 Exemptions The nonstructural components listed in Table 13.1-1 are exempt from the requirements of this chapter.

13.1.5 Premanufactured Modular Mechanical and Electrical Systems Premanufactured mechanical and electrical modules 6 ft (1.8 m) high and taller that are not otherwise prequalified in accordance with Chapter 13 and that contain or support mechanical and electrical components shall be designed in accordance with the provisions for nonbuilding structures similar to buildings in Chapter 15. Nonstructural components contained or supported within modular systems shall be designed in accordance with Chapter 13.

13.1.6 Application of Nonstructural Component Requirements to Nonbuilding Structures Nonbuilding structures (including storage racks and tanks) that are supported by other structures shall be designed in accordance with Chapter 15. Where Section 15.3 requires that seismic forces be determined in accordance with Chapter 13 and values for C_{AR} and R_{po} are not provided in Table 13.5-1 or 13.6-1, the term $\left[\frac{C_{AR}}{R_{po}}\right]$ in Equation (13.3-1) shall be taken as equal to $2.5/R$, where the value of R for the nonbuilding structure is obtained from Tables 15.4-1 or 15.4-2.

13.1.7 Reference Documents Where a reference document provides a basis for the earthquake-resistant design of a particular type of nonstructural component, that document is permitted to be used, subject to the approval of the Authority Having Jurisdiction and the following conditions:

1. The design earthquake forces shall not be less than those determined in accordance with Section 13.3.1.
2. Each nonstructural component's seismic interactions with all other connected components and with the supporting structure shall be accounted for in the design. The component shall accommodate drifts, deflections, and relative displacements determined in accordance with the applicable seismic requirements of this standard.
3. Nonstructural component anchorage requirements shall not be less than those specified in Section 13.4.

13.1.8 Reference Documents Using Allowable Stress Design Where a reference document provides a basis for the earthquake-resistant design of a particular type of component,

@seismicisolation
@seismicisolation

Table 13.1-1. Nonstructural Components Exempt from the Requirements of This Chapter.

Seismic Design Category (SDC)	Nonstructural Components Exempt from the Requirements of this Chapter
All Categories	• Furniture (except storage cabinets, as noted in Table 13.5-1) • Temporary components that remain in place for 180 days or less • Mobile units and equipment including components that are moved from one point in the structure to another during ordinary use
A	• All components
B	• Architectural Components, other than parapets, provided that the component Importance Factor, I_p, is equal to 1.0 • Mechanical and Electrical Components
C	• Mechanical and Electrical Components, provided that either ◦ The component Importance Factor, I_p, is equal to 1.0 and the component is positively attached to the structure; or ◦ The component weighs 20 lb (89 N) or less
D, E, F	• Mechanical and electrical components positively attached to the structure, provided that ◦ For discrete mechanical and electrical components, the component weighs 400 lb (1,779 N) or less, the center of mass is located 4 ft (1.22 m) or less above the adjacent floor level, flexible connections are provided between the component and associated ductwork, piping, and conduit, and the component Importance Factor, I_p, is equal to 1.0; or ◦ For discrete mechanical and electrical components, the component weighs 20 lb (89 N) or less; or ◦ For distribution systems, the component Importance Factor, I_p, is equal to 1.0 and the operating weight of the system is 5 lb/ft (73 N/m) or less. • Distribution systems included in the exceptions for conduit, cable tray, and raceways in Section 13.6.5, duct systems in 13.6.6, and piping and tubing systems in 13.6.7.3. Where in-line components, such as valves, in-line suspended pumps, and mixing boxes require independent support, they shall be addressed as discrete components and shall be braced considering the tributary contribution of the attached distribution system.

and the same reference document defines acceptance criteria in terms of allowable stresses rather than strengths, that reference document is permitted to be used. The allowable stress load combination shall consider dead, live, operating, and earthquake loads in addition to those in the reference document. The earthquake loads determined in accordance with Section 13.3.1 shall be multiplied by a factor of 0.7. The allowable stress design load combinations of Section 2.4 need not be used. The component shall also accommodate the relative displacements specified in Section 13.3.2.

13.2 GENERAL DESIGN REQUIREMENTS

13.2.1 Applicable Requirements for Architectural, Mechanical, and Electrical Components, Supports, and Attachments Architectural, mechanical, and electrical components, supports, and attachments shall comply with the sections referenced in Table 13.2-1. These requirements shall be satisfied by one of the following methods:

1. Project-specific design and documentation submitted for approval to the Authority Having Jurisdiction after review and acceptance by a registered design professional; or
2. Submittal of the manufacturer's certification that the component is seismically qualified by at least one of the following:
   (a) Analysis, or
   (b) Testing in accordance with the alternative set forth in Section 13.2.6, or
   (c) Experience data in accordance with the alternative set forth in Section 13.2.7.

13.2.2 Load Combinations Nonstructural components, including their supports and attachments, covered by this chapter and not otherwise exempt by Section 13.1.8 shall comply with Section 1.3, including consideration of load combinations of either Section 2.3 or 2.4, as appropriate. For the purposes of combining load effects, F_p shall be used per Section 12.4.2.1, and horizontal seismic design forces including overstrength shall be used per Section 12.4.3.1.

13.2.3 Special Certification Requirements for Designated Seismic Systems Certifications shall be provided for designated seismic systems assigned to Seismic Design Categories C through F as follows:

1. Active mechanical and electrical equipment that must remain operable following the design earthquake ground motion shall be certified by the manufacturer as operable whereby active parts or energized components shall be certified exclusively on the basis of approved shake table testing in accordance with Section 13.2.6 or experience data in accordance with Section 13.2.7, unless it can be

Table 13.2-1. Applicable Requirements for Architectural, Mechanical, and Electrical Components: Supports and Attachments.

Nonstructural Element (i.e., Component, Support, or Attachment)	General Design Requirements (Section 13.2)	Force and Displacement Requirements (Section 13.3)	Attachment Requirements (Section 13.4)	Architectural Component Requirements (Section 13.5)	Mechanical and Electrical Component Requirements (Section 13.6)
Architectural components and supports and attachments for architectural components	X	X	X	X	
Mechanical and electrical components	X	X	X		X
Supports and attachments for mechanical and electrical components	X	X	X		X

Note: X = applicable requirements.

@seismicisolation

shown that the component is inherently rugged by comparison with similar seismically qualified components. Evidence demonstrating compliance with this requirement shall be submitted for approval to the Authority Having Jurisdiction after review and acceptance by a registered design professional.

2. Components with hazardous substances and assigned a component Importance Factor, I_p, of 1.5 in accordance with Section 13.1.3 shall be certified by the manufacturer as maintaining containment following the design earthquake ground motion by (a) analysis, (b) approved shake table testing in accordance with Section 13.2.6, or (c) experience data in accordance with Section 13.2.7. Evidence demonstrating compliance with this requirement shall be submitted for approval to the Authority Having Jurisdiction after review and acceptance by a registered design professional.
3. Certification of components through analysis shall be limited to nonactive components and shall be based on seismic demand considering $\left[\frac{C_{AR}}{R_{po}}\right] = 2.5$. The value of R_μ shall be taken as 1.3 for components located above the grade plane.

EXCEPTION: If the period of the component, T_p, is less than or equal to 0.06 seconds, $\left[\frac{C_{AR}}{R_{po}}\right]$ may be taken as 1.0.

13.2.4 Consequential Damage The functional and physical interrelationship of components, their supports, and their effect on each other shall be considered so that the failure of an essential or nonessential architectural, mechanical, or electrical component shall not cause the failure of an essential architectural, mechanical, or electrical component. Where not otherwise established by analysis or test, required clearances for sprinkler system drops and sprigs shall not be less than those specified in Section 13.2.4.1.

13.2.4.1 Clearances between Equipment, Distribution Systems, Supports, and Sprinkler System Drops and Sprigs The installed clearance between any sprinkler drop or sprig and the following items shall be at least 3 in. (76 mm) in all directions:

1. Permanently attached equipment, including its structural supports and bracing; and
2. Other distribution systems, including their structural supports and bracing.

EXCEPTION: Sprinklers installed using flexible sprinkler hose need not meet the installed clearance requirement of this section.

13.2.5 Flexibility The design and evaluation of components, their supports, and their attachments shall consider their flexibility and their strength.

13.2.6 Testing Alternative for Seismic Capacity Determination As an alternative to the analytical requirements of Sections 13.2 through 13.6, testing shall be deemed an acceptable method to determine the seismic capacity of components and their supports and attachments. Seismic qualification by testing based on a nationally recognized testing standard procedure, such as ICC-ES AC 156, acceptable to the Authority Having Jurisdiction shall be deemed to satisfy the design and evaluation requirements provided that the substantiated seismic capacities equal or exceed the seismic demands determined in accordance with Sections 13.3.1 and 13.3.2. For the testing alternative, the maximum seismic demand determined in accordance with Equation (13.3-2) is not required to exceed $3.2I_pW_p$.

13.2.7 Experience Data Alternative for Seismic Capacity Determination As an alternative to the analytical requirements of Sections 13.2 through 13.6, use of experience data shall be deemed an acceptable method to determine the seismic capacity of components and their supports and attachments. Seismic qualification by experience data based on nationally recognized procedures acceptable to the Authority Having Jurisdiction shall be deemed to satisfy the design and evaluation requirements provided that the substantiated seismic capacities equal or exceed the seismic demands determined in accordance with Sections 13.3.1 and 13.3.2.

13.2.8 Construction Documents Where design of nonstructural components or their supports and attachments is required by Table 13.2-1, such design shall be shown in construction documents prepared by a registered design professional for use by the owner, Authorities Having Jurisdiction, contractors, and inspectors.

13.2.9 Supported Nonstructural Components with Greater than or Equal to 20% Combined Weight For the condition where the weight of a nonstructural component is equal to or greater than 20% of the combined effective seismic weight, W, of the nonstructural component and the supporting structure, an analysis combining the structural characteristics of both the nonstructural component and the supporting structure shall be performed to determine the seismic design forces. The nonstructural component and the supporting structure shall be designed for forces and displacements determined in accordance with Chapter 12 or Section 15.5, as appropriate, with the R value of the combined system taken as the lesser of $0.40\left[\frac{C_{AR}}{R_{po}}\right]$ of the nonstructural component or the R value of the supporting structure. The nonstructural component and attachments shall be designed for the forces and displacements resulting from the combined analysis. Design criteria for the nonstructural component shall otherwise be in accordance with this chapter.

EXCEPTION: Where the ratio of the fundamental period of the nonstructural component and its attachment (to the structure) to the fundamental period of the supporting structure (including the lumped weight of the nonstructural component) is less than 0.5 or greater than 2.0, the supporting structure is permitted to be designed in accordance with the requirements of Chapter 12 or Section 15.5, as appropriate. The supported nonstructural component shall follow the requirements of Chapter 13 as if the weight of the nonstructural component were less than 20% of the combined effective seismic weight, W, of the nonstructural component and supporting structure.

13.3 SEISMIC DEMANDS ON NONSTRUCTURAL COMPONENTS

13.3.1 Horizontal Seismic Design Forces The horizontal seismic design force, F_p, shall be applied at the component's center of gravity and distributed relative to the component's mass distribution. The redundancy factor, ρ, is permitted to be taken as equal to 1.

The directions of F_p used shall be those that produce the most critical load effects on the component, the component supports, and attachments. Alternatively, it is permitted to use the more severe of the following two load cases:

- Case 1: A combination of 100% of F_p in any one horizontal direction and 30% of F_p in a perpendicular horizontal direction applied simultaneously.
- Case 2: The combination from Case 1 rotated 90 degrees.

@seismicisolation

The horizontal seismic design force shall be calculated as

$$F_p = 0.4 S_{DS} I_p W_p \left[\frac{H_f}{R_\mu}\right] \left[\frac{C_{AR}}{R_{po}}\right] \quad (13.3\text{-}1)$$

F_p is not required to be taken as greater than

$$F_p = 1.6 S_{DS} I_p W_p \quad (13.3\text{-}2)$$

and shall not be taken as less than

$$F_p = 0.3 S_{DS} I_p W_p \quad (13.3\text{-}3)$$

where

F_p = Seismic design force;
S_{DS} = Spectral acceleration, short period, as determined in accordance with Section 11.4.5;
I_p = Component Importance Factor as determined in accordance with Section 13.1.3;
W_p = Component operating weight;
H_f = Factor for force amplification as a function of height in the structure as determined in Section 13.3.1.1;
R_μ = Structure ductility reduction factor as determined in Section 13.3.1.2;
C_{AR} = Component resonance ductility factor that converts the peak floor or ground acceleration into the peak component acceleration, as determined in Section 13.3.1.3; and
R_{po} = Component strength factor as determined in Section 13.3.1.4.

13.3.1.1 Amplification with Height, H_f For nonstructural components supported at or below grade plane, the factor for force amplification with height H_f, is 1.0. For components supported above grade plane by a building or nonbuilding structure, H_f is permitted to be determined by Equation (13.3-4) or Equation (13.3-5). Where the approximate fundamental period of the supporting building or nonbuilding structure is unknown, H_f is permitted to be determined by Equation (13.3-5).

$$H_f = 1 + a_1\left(\frac{z}{h}\right) + a_2\left(\frac{z}{h}\right)^{10} \quad (13.3\text{-}4)$$

$$H_f = 1 + 2.5\left(\frac{z}{h}\right) \quad (13.3\text{-}5)$$

where

$a_1 = 1/T_a \le 2.5$;
$a_2 = [1 - (0.4/T_a)^2] \ge 0$;
z = Height above the base of the structure to the point of attachment of the component. For items at or below the base, z shall be taken as 0. The value of $\frac{z}{h}$ need not exceed 1.0;
h = Average roof height of structure with respect to the base; and
T_a = Lowest approximate fundamental period of the supporting building or nonbuilding structure in either orthogonal direction. For structures with combinations of seismic force-resisting systems (SFRSs), the SFRS that produces the lowest value of T_a shall be used.

For the purposes of computing H_f, T_a is determined using Equation (12.8-8) for buildings. Where the SFRS is unknown, T_a is permitted to be determined by Equation (12.8-8) using the approximate period parameters for "all other structural systems."

For nonbuilding structures, T_a is permitted to be taken as

(a) The period of the nonbuilding structure, T, determined using the structural properties and deformation characteristics of the resisting elements in a properly substantiated analysis as indicated in Section 12.8.2; or
(b) The period of the nonbuilding structure, T, determined using Equation (15.4-6); or
(c) The period T_a determined by Equation (12.8-8), using the approximate period parameters for "all other structural systems."

13.3.1.2 Structure Ductility Reduction Factor, R_μ For components supported by a building or nonbuilding structure, the reduction factor for ductility of the supporting structure, R_μ, is calculated as

$$R_\mu = [1.1R/(I_e\Omega_0)]^{1/2} \ge 1.3 \quad (13.3\text{-}6)$$

where

I_e = Importance Factor as prescribed in Section 11.5.1 for the building or nonbuilding structure supporting the component;
R = Response modification factor for the building or nonbuilding structure supporting the component, from Table 12.2-1, 15.4-1, or 15.4-2; and
Ω_0 = Overstrength factor for the building or nonbuilding structure supporting the component, from Table 12.2-1, 15.4-1, or 15.4-2.

For components supported at or below grade plane, R_μ shall be taken as 1.0. When the SFRS of the building or nonbuilding structure is not specified, R_μ shall be taken as 1.3 for components above grade plane. When the SFRS of the building or nonbuilding structure is not listed in Table 12.2-1, 15.4-1, or 15.4-2, R_μ shall be taken as 1.3 for components above grade plane, unless seismic design parameters for the SFRS have been approved by the Authority Having Jurisdiction.

If the building or nonbuilding structure supporting the component contains combinations of SFRSs in different directions, or vertical combinations of SFRSs, the structure ductility reduction factor for the entire structure shall be based on the SFRS that produces the lowest value of R_μ. Where a nonbuilding structure type listed in Table 15.4-1 has multiple entries based on permissible height increases, the value of R_μ is permitted to be determined using values of R and Ω_0 for the "with permitted height increase" entry.

13.3.1.3 Component Resonance Ductility Factor, C_{AR} Components shall be assigned a component resonance ductility factor, C_{AR}, based on whether the component is supported at or below grade plane, or is supported above grade plane by a building or nonbuilding structure. Components that are in or supported by a building or nonbuilding structure and are at or below grade plane are considered supported at or below grade. All other components in or supported by a building or nonbuilding structure are considered supported above grade.

Architectural components shall be assigned a component resonance ductility factor in Table 13.5-1.

Mechanical and electrical equipment shall be assigned a component resonance ductility factor in Table 13.6-1. The component resonance ductility factor for mechanical and electrical equipment mounted on the equipment support structures or platforms shall not be less than the component resonance ductility factor used for the equipment support structure or platform itself.

@seismicisolation

The component resonance ductility factor for equipment support structures or platforms shall be determined in accordance with Section 13.6.4.6. The weight of supported mechanical and electrical components shall be included when calculating the component operating weight, W_p, of equipment support structures or platforms.

Distribution systems shall be assigned component resonance ductility factors in Table 13.6-1, to be used for the design of the distribution system itself (e.g., the piping, ducts, and raceways). The component resonance ductility factor for distribution system supports shall be determined in accordance with Section 13.6.4.7

13.3.1.4 Component Strength, R_{po} The component strength factor, R_{po}, for nonstructural components is given in Table 13.5-1 or 13.6-1.

13.3.1.5 Nonlinear Response History Analysis In lieu of the forces determined in accordance with Equation (13.3-1), the nonlinear response history analysis procedures of Chapters 16, 17, and 18 may be used to determine the seismic design force for nonstructural components. Where the dynamic properties of the nonstructural component are not explicitly modeled in the nonlinear response history analysis, the seismic design force, *Fp*, shall be calculated as

$$F_p = I_p W_p a_i \left[\frac{C_{AR}}{R_{po}}\right] \tag{13.3-7}$$

where a_i is the maximum acceleration at level i obtained from the nonlinear response history analysis at the Design Earthquake ground motion. When a_i is determined using nonlinear response history analysis, a suite of not less than seven ground motions shall be used. If the supporting structure is designed using nonlinear response history analysis, the entire suite of ground motions used to design the structure shall be used to determine a_i. The value of the parameter a_i shall be taken as the mean of the maximum values of acceleration at the center of mass of the support level, obtained from each analysis. The upper and lower limits of F_p determined by Equations (13.3-2) and (13.3-3) shall apply.

13.3.1.6 Vertical Seismic Force The component, including its supports and attachments, shall be designed for a concurrent vertical seismic design force equal to E_v per Section 12.4.2.2.

EXCEPTION: The concurrent vertical seismic force need not be considered for lay-in access floor panels and lay-in ceiling panels.

13.3.1.7 Nonseismic Loads Where nonseismic loads on nonstructural components exceed F_p, such loads shall govern the strength design, but the detailing requirements and limitations prescribed in this chapter shall apply.

13.3.2 Seismic Relative Displacements The effects of seismic relative displacements shall be considered in combination with displacements caused by other loads as appropriate. Seismic relative displacements, D_{pI}, shall be calculated as

$$D_{pI} = D_p I_e \tag{13.3-8}$$

where I_e is the Importance Factor in Section 11.5.1, and D_p is the displacement determined in accordance with the equations set forth in Sections 13.3.2.1 and 13.3.2.2.

13.3.2.1 Displacements within Structures For two connection points on the same structure A or the same structural system, one at a height h_x and the other at a height h_y, D_p shall be determined as

$$D_p = \delta_{xA} - \delta_{yA} \tag{13.3-9}$$

where

D_p = Relative seismic displacement the component must be designed to accommodate;
δ_{xA} = Deflection at building level x of structure A, determined in accordance with Equation (12.8-16); and
δ_{yA} = Deflection at building level y of structure A, determined in accordance with Equation (12.8-16).

Alternatively, D_p is permitted to be determined using the linear dynamic procedures described in Section 12.9. For structures in which the story drift associated with the Design Earthquake Displacement does not exceed the allowable story drift as defined in Table 12.12-1, D_p is not required to be taken as greater than

$$D_p = \frac{(h_x - h_y)\Delta_{aA}}{h_{sx}} \tag{13.3-10}$$

where Δ_{aA} is the allowable story drift for structure A as designed in Table 12.12-1, and h_{sx} is the story height used in the definition of the allowable drift, Δ_a, in Table 12.12-1.

Where single-story structures are designed in accordance with note a of Table 12.12-1, Equation (13.3-10) shall not apply.

13.3.2.2 Displacements between Structures For two connection points on separate structures A and B or separate structural systems, one at a height h_x and the other at a height h_y, D_p shall be determined as

$$D_p = |\delta_{xA}| + |\delta_{yB}| \tag{13.3-11}$$

For structures in which the story drifts associated with the Design Earthquake Displacement does not exceed the allowable story drift as defined in Table 12.12-1, the drift is not required to be taken as greater than

$$D_p = \frac{h_x \Delta_{aA}}{h_{sx}} + \frac{h_y \Delta_{aB}}{h_{sx}} \tag{13.3-12}$$

Where single-story structures are designed in accordance with note a of Table 12.12-1, Equation (13.3-12) shall not apply where

D_p = Relative seismic displacement the component must be designed to accommodate;
δ_{xA} = Deflection at building level x of structure A at the Design Earthquake Displacement; determined in accordance with Equation (12.8-16);
δ_{yA} = Deflection at building level y of structure A at the Design Earthquake Displacement; determined in accordance with Equation (12.8-16);
δ_{yB} = Deflection at building level y of structure B at the Design Earthquake Displacement; determined in accordance with Equation (12.8-16);
h_x = Height of level x to which upper connection point is attached;
h_y = Height of level y to which lower connection point is attached;
Δ_{aA} = Allowable story drift for structure A as defined in Table 12.12-1;
Δ_{aB} = Allowable story drift for structure B as defined in Table 12.12-1; and

@seismicisolation

h_{sx} = Story height used in the definition of allowable drift, Δ_a, in Table 12.12-1. Note that Δ_a/h_{sx} is the drift index.

The effects of seismic relative displacements shall be considered in combination with displacements caused by other loads as appropriate.

13.3.3 Component Period The fundamental period, T_p, of the nonstructural component, including its supports and attachment to the structure, shall be determined by the following equation, provided the component, supports, and attachment can be reasonably represented analytically by a simple single-degree-of-freedom spring-and-mass system:

$$T_p = 2\pi\sqrt{\frac{W_p}{K_p g}} \tag{13.3-13}$$

where

T_p = Component fundamental period,
W_p = Component operating weight,
g = Gravitational acceleration, and
K_p = Combined stiffness of the component, supports, and attachments, determined in terms of load per unit deflection at the center of gravity of the component.

Alternatively, the fundamental period of the component, T_p, in seconds is permitted to be determined from experimental test data or by a properly substantiated analysis.

13.4 NONSTRUCTURAL COMPONENT ANCHORAGE AND ATTACHMENT

Nonstructural components and their supports shall be attached (or anchored) to the structure in accordance with the requirements of this section, and the attachment shall satisfy the requirements for the parent material as set forth elsewhere in this standard.

Except where permitted in Section 13.6.12, component attachments shall be bolted, welded, or otherwise positively fastened without consideration of frictional resistance produced by the effects of gravity. A continuous load path of sufficient strength and stiffness between the component and the supporting structure shall be provided. Local elements of the structure, including connections, shall be designed and constructed for the component forces where they control the design of the elements or their connections. The component forces shall be those determined in Section 13.3.1. The design documents shall include sufficient information relating to the attachments to verify compliance with the requirements of this section.

13.4.1 Design Force in the Attachment The force in the attachment shall be determined based on the prescribed forces and displacements for the component as determined in Sections 13.3.1 and 13.3.2.

13.4.2 Anchors in Concrete or Masonry When it is required to apply the seismic load effects including overstrength in Section 12.4.3, Ω_0 shall be taken as the anchorage overstrength factor, Ω_{0p}, given in Tables 13.5-1 and 13.6-1.

13.4.2.1 Anchors in Concrete Anchors in concrete shall be designed in accordance with Chapter 17 of ACI 318.

13.4.2.2 Anchors in Masonry Anchors in masonry shall be designed in accordance with TMS 402. Anchors shall be designed to be governed by the tensile or shear strength of a ductile steel element.

EXCEPTION: Anchors shall be permitted to be designed so that either

1. The support or component that the anchor is connecting to the structure undergoes ductile yielding at a load level corresponding to anchor forces not greater than the design strength of the anchors, or
2. The anchors shall be designed to resist the load combinations in accordance with Section 13.2.2, including Ω_{0p} as given in Tables 13.5-1 and 13.6-1.

13.4.2.3 Post-Installed Anchors in Concrete and Masonry Post-installed anchors in concrete shall be prequalified for seismic applications in accordance with ACI 355.2 or other approved qualification procedures. Post-installed anchors in masonry shall be prequalified for seismic applications in accordance with approved qualification procedures.

13.4.3 Installation Conditions Determination of forces in attachments shall take into account the expected conditions of installation, including eccentricities and prying effects.

13.4.4 Multiple Attachments Determination of force distribution of multiple attachments at one location shall take into account the stiffness and ductility of the component, component supports, attachments, and structure, and the ability to redistribute loads to other attachments in the group. Designs of anchorage in concrete in accordance with Chapter 17 of ACI 318 shall be considered to satisfy this requirement.

13.4.5 Power-Actuated Fasteners Power-actuated fasteners in concrete or steel shall not be used for sustained tension loads or for brace applications in Seismic Design Category D, E, or F unless approved for seismic loading. Power-actuated fasteners in masonry are not permitted unless approved for seismic loading.

EXCEPTIONS:

1. Power-actuated fasteners in concrete used for support of acoustical tile or lay-in panel suspended ceiling applications and distributed systems where the service load on any individual fastener does not exceed 90 lb (400 N), and
2. Power-actuated fasteners in steel where the service load on any individual fastener does not exceed 250 lb (1,112 N).

13.4.6 Friction Clips Friction clips in Seismic Design Category D, E, or F shall not be used for supporting permanent loads in addition to resisting seismic forces. C-type beam and large flange clamps are permitted for hangers, provided they are equipped with restraining straps equivalent to those specified in NFPA 13, Section 9.3.7. Lock nuts or equivalent shall be provided to prevent loosening of threaded connections.

13.5 ARCHITECTURAL COMPONENTS

13.5.1 General. Architectural components, and their supports and attachments, shall satisfy the requirements of this section. Appropriate coefficients shall be selected from Table 13.5-1.

EXCEPTION: Components supported by chains or otherwise suspended from the structure are not required to satisfy the seismic force and relative displacement requirements, provided they meet all of the following criteria:

1. The design load for such items shall be equal to 1.4 times the operating weight acting down with a simultaneous horizontal load equal to 1.4 times the operating weight. The horizontal load shall be applied in the direction that results in the most critical loading for design.

@seismicisolation

Table 13.5-1. Coefficients for Architectural Components.

Architectural Component	C_{AR}		R_{po}	Ω_{op}[a]
	Supported at or below grade plane	Supported above grade plane by a structure		
Interior nonstructural walls and partitions[b]				
Light frame ≤ 9 ft (2.74 m) in height	1	1	1.5	2
Light frame > 9 ft (2.74 m) in height	1.4	1.4	1.5	2
Reinforced masonry	1	1	1.5	2
All other walls and partitions	2.2	2.8	1.5	1.5
Cantilever elements (unbraced or braced to structural frame below its center of mass)				
Parapets and cantilever interior nonstructural walls	1.8	2.2	1.5	1.75
Chimneys where laterally braced or supported by the structural frame	1.8	2.2	1.5	1.75
Cantilever elements (braced to structural frame above its center of mass)				
Parapets	1	1	1.5	2
Chimneys	1	1	1.5	2
Exterior nonstructural walls[b]	1	1	1.5	2
Exterior nonstructural wall elements and connections[b]				
Wall element	1	1	1.5	2
Body of wall panel connections	1	1	1.5	2
Fasteners of the connecting system	2.2	2.8	1.5	1
Veneer				
Limited-deformability elements and attachments	1	1	1.5	2
Low-deformability elements and attachments	1	1	1.5	2
Penthouses (except where framed by an extension of the building frame)				
Seismic force-resisting systems with $R \geq 6$	N/A	1.4	2	2
Seismic force-resisting systems with $4 \leq R < 6$	N/A	2.2	2	1.75
Seismic force-resisting systems with $R < 4$	N/A	2.8	2	1.5
Other systems	N/A	2.8	1.5	1.5
Ceilings				
All	1	1	1.5	2
Cabinets				
Permanent floor-supported storage cabinets more than 6 ft (1.8 m) tall, including contents	1	1	1.5	2
Permanent floor-supported library shelving, book stacks, and bookshelves more than 6 ft (1.8 m) tall, including contents	1	1	1.5	2
Laboratory equipment	1	1	1.5	2
Access floors				
Special access floors (designed in accordance with Section 13.5.7.2)	1	1	2	2
All other	2.2	2.8	1.5	1.5
Appendages and ornamentations	1.8	2.2	1.5	1.75
Signs and billboards	1.8	2.2	1.5	1.75
Other rigid components	1	1	1.5	2
Other flexible components				
High-deformability elements and attachments	1.4	1.4	1.5	2
Limited-deformability elements and attachments	1.8	2.2	1.5	1.75
Low-deformability materials and attachments	2.2	2.8	1.5	1.5
Egress stairways not part of the building seismic force-resisting system	1	1	1.5	2
Egress stairs and ramp fasteners and attachments	1.8	2.2	1.5	1.75

[a] Overstrength factor, where required for nonductile anchorage to concrete and masonry (see Section 13.4.2).
[b] Where flexible diaphragms provide lateral support for concrete or masonry walls and partitions, *the design forces for anchorage to the diaphragm shall be as specified in Section 12.11.2*.
Note: N/A = not applicable.

2. Seismic interaction effects shall be considered in accordance with Section 13.2.4.
3. The connection to the structure shall allow a 360-degree range of motion in the horizontal plane.

13.5.2 Forces and Displacements All architectural components, and their supports and attachments, shall be designed for the seismic forces defined in Section 13.3.1.

Architectural components that could pose a life-safety hazard shall be designed to accommodate the seismic relative displacement requirements of Section 13.3.2. Architectural components shall be designed considering vertical deflection caused by joint rotation of cantilever structural members.

13.5.3 Exterior Nonstructural Wall Elements and Connections Exterior nonstructural wall panels or elements that are attached to or enclose the structure shall be designed

@seismicisolation

to accommodate the seismic relative displacements defined in Section 13.3.2 and movements caused by temperature changes. Such elements shall be supported by means of positive and direct structural supports or by mechanical connections and fasteners in accordance with the following requirements:

1. Connections and panel joints shall allow for the story drift caused by relative seismic displacements, D_{pI}, determined in Section 13.3.2, or 0.5 in. (13 mm), whichever is greater.
2. Connections accommodating story drift through sliding mechanisms or bending of threaded steel rods shall satisfy all of the following.
   (a) Threaded rods or bolts shall be fabricated of low-carbon or stainless steel. Where cold-worked carbon steel threaded rods are used, the rods as fabricated shall meet or exceed the reduction of area, elongation, and tensile strength requirements of ASTM F1554, Grade 36. Grade 55 rods shall also be permitted provided they meet the requirements of Supplement 1; and
   (b) Where threaded rods connecting the panel to the supports are used in connections using slotted or oversize holes, the rods shall have length-to-diameter ratios of 4 or less, where the length is the clear distance between the nuts or threaded plates. The slots or oversized holes shall be proportioned to accommodate the full in-plane design story drift in each direction, the nuts shall be installed finger-tight, and a positive means to prevent the nut from backing off shall be used; and
   (c) Connections that accommodate story drift by bending of threaded rods shall satisfy

$$(L/d)/D_{pI} \geq 6.0(1/\text{in.}) \qquad (13.5\text{-}1)$$

$$(L/d)/D_{pI} \geq 0.24(1/\text{mm}) \qquad (13.5\text{-}1.\text{SI})$$

where

L = Clear length of rod between nuts or threaded plates [in. (mm)],
d = Rod diameter [in. (mm)], and
D_{pI} = Relative seismic displacement the connection must be designed to accommodate [in. (mm)].

3. The connecting member itself shall have sufficient ductility and rotation capacity to preclude fracture of the concrete or brittle failures at or near welds.
4. All fasteners in the connecting system, such as bolts, inserts, welds, and dowels, and the body of the connectors, shall be designed for the force, F_p, determined by Section 13.3.1 using the applicable design coefficients taken from Table 13.5-1, applied at the center of mass of the panel. The connecting system shall include both the connections between the wall panels or elements and the structure, and the interconnections between wall panels or elements.
5. Where anchorage is achieved using flat straps embedded in concrete or masonry, such straps shall be attached to or hooked around reinforcing steel or otherwise terminated so as to effectively transfer forces to the reinforcing steel or to ensure that pullout of anchorage is not the initial failure mechanism.

13.5.4 Glass Glass in glazed curtain walls and storefronts shall be designed and installed to accommodate without breakage or dislodgement the relative-displacement requirement of Section 13.5.9.

Where glass is secured to the window system framing by means of structural sealant glazing, the requirements contained in the reference standards listed in Table 13.5-2 shall also apply.

13.5.5 Out-of-Plane Bending Transverse or out-of-plane bending or deformation of a component or system that is subjected to forces as determined in Section 13.5.2 shall not exceed the deflection capability of the component or system.

13.5.6 Suspended Ceilings Suspended ceilings shall be in accordance with this section.

EXCEPTIONS:

1. Suspended ceilings with areas less than or equal to 144 ft^2 (13.4 m^2) that are surrounded by walls or soffits that are laterally braced to the structure above are exempt from the requirements of this section.
2. Suspended ceilings constructed of screw- or nail-attached gypsum board on one level that are surrounded by and connected to walls or soffits that are laterally braced to the structure above are exempt from the requirements of this section.

13.5.6.1 Seismic Forces The weight of the ceiling, W_p, shall include the ceiling grid; ceiling tiles or panels; light fixtures if attached to, clipped to, or laterally supported by the ceiling grid; and other components that are laterally supported by the ceiling. W_p shall be taken as not less than 4 lb/ft^2 (192 N/m^2).

The seismic force, F_p, shall be transmitted through the ceiling attachments to the building structural elements or the ceiling–structure boundary.

13.5.6.2 Industry Standard Construction for Acoustical Tile or Lay-In Panel Ceilings Unless designed in accordance with Section 13.5.6.3, or seismically qualified in accordance with Section 13.2.6 or 13.2.7, acoustical tile or lay-in panel ceilings shall be designed and constructed in accordance with this section.

13.5.6.2.1 Seismic Design Category C. Acoustical tile or lay-in panel ceilings in structures assigned to Seismic Design Category

Table 13.5-2. Reference Standards for Structural Sealant Glazing.

ASTM C1087, *Test Method for Determining Compatibility of Liquid-Applied Sealants with Accessories Used in Structural Glazing Systems*
ASTM C1135, *Test Method for Determining Tensile Adhesion Properties of Structural Sealants*
ASTM C1184, *Specification for Structural Silicone Sealants*
ASTM C1265, *Test Method for Determining the Tensile Properties of an Insulating Glass Edge Seal for Structural Glazing Applications*
ASTM C1294, *Test Method for Compatibility of Insulating Glass Edge Sealants with Liquid-Applied Glazing Materials*
ASTM C1369, *Specification for Secondary Edge Sealants for Structurally Glazed Insulating Glass Units*

@seismicisolation

C shall be designed and installed in accordance with ASTM C635, ASTM C636, and ASTM E580, Section 4, Seismic Design Category C.

13.5.6.2.2 Seismic Design Categories D through F. Acoustical tile or lay-in panel ceilings in structures assigned to Seismic Design Categories D, E, and F shall be designed and installed in accordance with ASTM C635, ASTM C636, and ASTM E580, Section 5, Seismic Design Categories D, E, and F, as modified by this section.

Acoustical tile or lay-in panel ceilings shall also comply with the following:

(a) The width of the perimeter supporting closure angle or channel shall be not less than 2.0 in. (50 mm), unless qualified perimeter supporting clips are used. Closure angles or channels shall be screwed or otherwise positively attached to wall studs or other supporting structures. Perimeter supporting clips shall be qualified in accordance with approved test criteria per Section 13.2.6. Perimeter supporting clips shall be attached to the supporting closure angle or channel with a minimum of two screws per clip and shall be installed around the entire ceiling perimeter. In each orthogonal horizontal direction, one end of the ceiling grid shall be attached to the closure angle, channel, or perimeter supporting clip. The other end of the ceiling grid in each horizontal direction shall have a minimum 0.75 in. (19 mm) clearance from the wall and shall rest on and be free to slide on a closure angle, channel, or perimeter supporting clip.

(b) For ceiling areas exceeding 2,500 ft^2 (232 m^2), a seismic separation joint or full-height partition that breaks the ceiling up into areas not exceeding 2,500 ft^2 (232 m^2), each with a ratio of the long to short dimension less than or equal to 4, shall be provided, unless structural analyses are performed of the ceiling bracing system for the prescribed seismic forces which demonstrate that ceiling penetrations and closure angles or channels provide sufficient clearance to accommodate the anticipated lateral displacement. Each area shall be provided with closure angles or channels in accordance with Section 13.5.6.2.2.a and horizontal restraints or bracing.

13.5.6.3 Integral Construction As an alternative to providing large clearances around sprinkler system penetrations through ceilings, the sprinkler system and ceiling grid are permitted to be designed and tied together as an integral unit. Such a design shall consider the mass and flexibility of all elements involved, including the ceiling, sprinkler system, light fixtures, and mechanical (HVACR) appurtenances. Such design shall be performed by a registered design professional.

13.5.7 Access Floors

13.5.7.1 General The weight of the access floor, W_p, shall include the weight of the floor system, 100% of the weight of all equipment fastened to the floor, and 25% of the weight of all equipment supported by but not fastened to the floor. The seismic force, F_p, shall be transmitted from the top surface of the access floor to the supporting structure.

Overturning effects of equipment fastened to the access floor panels also shall be considered. The ability of "slip on" heads for pedestals shall be evaluated for suitability to transfer overturning effects of equipment.

Where checking individual pedestals for overturning effects, the maximum concurrent axial load shall not exceed the portion of W_p assigned to the pedestal under consideration.

13.5.7.2 Special Access Floors Access floors shall be considered to be "special access floors" if they are designed to comply with the following considerations:

1. Connections transmitting seismic loads consist of mechanical fasteners, anchors satisfying the requirements of Chapter 17 of ACI 318, welding, or bearing. Design load capacities shall comply with recognized design codes and/or certified test results.
2. Seismic loads are not transmitted by friction, power-actuated fasteners, adhesives, or by friction produced solely by the effects of gravity.
3. The design analysis of the bracing system includes the destabilizing effects of individual members buckling in compression.
4. Bracing and pedestals are of structural or mechanical shapes produced to ASTM specifications that specify minimum mechanical properties. Electrical tubing shall not be used.
5. Floor stringers are used that are designed to carry axial seismic loads and that are mechanically fastened to the supporting pedestals.

13.5.8 Partitions

13.5.8.1 General Partitions that are tied to the ceiling, and all partitions greater than 6 ft (1.8 m) high, shall be laterally braced to the building structure. Such bracing shall be independent of any ceiling lateral force bracing. Bracing shall be spaced to limit horizontal deflection at the partition head, to be compatible with ceiling deflection requirements as determined in Section 13.5.6 for suspended ceilings and elsewhere in this section for other systems.

EXCEPTION: Partitions that meet all of the following conditions:

1. The partition height does not exceed 9 ft (2.7 m).
2. The linear weight of the partition does not exceed 10 lb (0.479 kN) times the height in ft (m) of the partition.
3. The partition horizontal seismic load does not exceed 5 lb/ft^2 (0.24 kN/m^2).

13.5.8.2 Glass Glass in glazed partitions shall be designed and installed in accordance with Section 13.5.9.

13.5.9 Glass in Glazed Curtain Walls, Glazed Storefronts, and Glazed Partitions

13.5.9.1 General Glass in glazed curtain walls, glazed storefronts, and glazed partitions shall meet the relative displacement requirement of Equation (13.5-2):

$$\Delta_{\text{fallout}} \geq 1.25 D_{pI} \tag{13.5-2}$$

or 0.5 in. (13 mm), whichever is greater, where Δ_{fallout} is the relative seismic displacement (drift) at which glass fallout from the curtain wall, storefront wall, or partition occurs (Section 13.5.9.2); and D_{pI} is the relative seismic displacement the component must be designed to accommodate (Section 13.3.2). D_{pI} shall be applied over the height of the glass component under consideration.

@seismicisolation

EXCEPTIONS:

1. Glass need not comply with this requirement if it has sufficient clearances from its frame such that physical contact between the glass and frame does not occur at the design drift:

$$D_{\text{clear}} \geq 1.25D_{pI} \tag{13.5-3}$$

where D_{clear} is the relative horizontal (drift) displacement, measured over the height of the glass panel under consideration, which causes initial glass-to-frame contact. For rectangular glass panels within a rectangular wall frame,

$$D_{\text{clear}} = 2c_1\left(1 + \frac{h_p c_2}{b_p c_1}\right)$$

where

h_p = Height of the rectangular glass panel,
b_p = Width of the rectangular glass panel,
c_1 = Average of the clearances (gaps) on both sides between the vertical glass edges and the frame, and
c_2 = Average of the clearances (gaps) at the top and bottom between the horizontal glass edges and the frame.

2. Fully tempered monolithic glass in Risk Categories I, II, and III located no more than 10 ft (3 m) above a walking surface need not comply with this requirement.
3. Annealed or heat-strengthened laminated glass in single thickness with interlayer no less than 0.030 in. (0.76 mm) that is captured mechanically in a wall system glazing pocket and whose perimeter is secured to the frame by a wet-glazed, gunable, curing elastomeric sealant perimeter bead of 0.5 in. (13 mm) minimum glass contact width, or other approved anchorage system, need not comply with this requirement.

13.5.9.2 Seismic Drift Limits for Glass Components Δ_{fallout}, the drift causing glass fallout from the curtain wall, storefront, or partition, shall be determined in accordance with AAMA 501.6 or by engineering analysis.

13.5.10 Egress Stairs and Ramps Egress stairs and ramps not part of the seismic force-resisting system (SFRS) of the structure to which they are attached shall be detailed to accommodate the seismic relative displacements, D_{pI}, defined in Section 13.3.2, including diaphragm deformation. The net relative displacement shall be assumed to occur in any horizontal direction. Such elements shall be supported by means of positive and direct structural supports or by mechanical connections and fasteners in accordance with the following requirements:

(a) Sliding connections with slotted or oversize holes, sliding bearing supports with keeper assemblies or end stops, and connections that permit movement by deformation of metal attachments, shall accommodate a displacement D_{pI}, but not less than 0.5 in. (13 mm), without loss of vertical support or inducement of displacement-related compression forces in the stair.
(b) Sliding bearing supports without keeper assemblies or end stops shall be designed to accommodate a displacement $1.5D_{pI}$, but not less than 1.0 in. (25 mm), without loss of vertical support. Breakaway restraints are permitted if their failure does not lead to loss of vertical support.
(c) Metal supports shall be designed with rotation capacity to accommodate seismic relative displacements as defined in item (b). The strength of such metal supports shall not be limited by bolt shear, weld fracture, or other brittle modes.
(d) All fasteners and attachments such as bolts, inserts, welds, dowels, and anchors shall be designed for the seismic design forces determined in accordance with Section 13.3.1 using the applicable design coefficients as given in Table 13.5-1.

EXCEPTION: If sliding or ductile connections are not provided to accommodate seismic relative displacements, the stiffness and strength of the stair or ramp structure shall be included in the building structural model of Section 12.7.3, and the stair shall be designed with Ω_0 corresponding to the SFRS but not less than 2-1/2.

13.5.11 Penthouses and Rooftop Structures Penthouses and rooftop structures shall be designed in accordance with this section. The horizontal seismic design force, F_p, shall be determined in accordance with Section 13.3.1, using the design coefficients listed in Table 13.5-1.

EXCEPTION: Penthouses and rooftop structures framed by an extension of the building frame and designed in accordance with the requirements of Chapter 12.

13.5.11.1 Seismic Force-Resisting Systems for Penthouses and Rooftop Structures The seismic force-resisting system for penthouses and rooftop structures shall conform to one of the types indicated in Table 12.2-1 or Table 15.4-1. The structural systems used shall be in accordance with the structural system limitations noted in the tables and shall be designed and detailed in accordance with the specific requirements for the system as set forth in the applicable reference documents listed in Table 12.2-1 or 15.4-1 and the additional requirements set forth in Chapter 14. Height limits for penthouses and rooftop structures shall be measured from the top of the roof structure to the average height of the penthouse roof.

EXCEPTION: Penthouses and rooftop structures designed using the coefficients for Other Systems in Table 13.5-1 and which also conform to the requirements of relevant material standards need not conform to one of the types indicated in Table 12.2-1 or 15.4-1. The height limit for penthouses and rooftop structures designed using the coefficients for Other Systems shall be 28 ft (8.5 m).

13.6 MECHANICAL AND ELECTRICAL COMPONENTS

13.6.1 General Mechanical and electrical components and their supports shall satisfy the requirements of this section. The attachment of mechanical and electrical components and their supports to the structure shall meet the requirements of Section 13.4. Appropriate coefficients shall be selected from Table 13.6-1.

EXCEPTION: Light fixtures, lighted signs, and ceiling fans not connected to ducts or piping, which are supported by chains or otherwise suspended from the structure, are not required to satisfy the seismic force and relative displacement requirements provided they meet all of the following criteria:

1. The design load for such items shall be equal to 1.4 times the operating weight acting down with a simultaneous horizontal load equal to 1.4 times the operating weight.

@seismicisolation

[a] Components mounted on vibration isolators shall have a bumper restraint or snubber in each horizontal direction. The design force shall be taken as $2F_p$ if the nominal clearance (air gap) between the equipment support frame and restraint is greater than 0.25 in. (6 mm). If the nominal clearance specified on the construction documents is not greater than 0.25 in. (6 mm), the design force is permitted to be taken as F_p.

[b] Overstrength factor as required for anchorage to concrete and masonry (see Section 13.4.2).

The horizontal load shall be applied in the direction that results in the most critical loading for the design.

2. Seismic interaction effects shall be considered in accordance with Section 13.2.4.
3. The connection to the structure shall allow a 360-degree range of motion in the horizontal plane.

Where design of mechanical and electrical components for seismic effects is required, consideration shall be given to the dynamic effects of the components, their contents, and where appropriate, their supports and attachments. In such cases, the interaction between the components and the supporting structures, including other mechanical and electrical components, shall also be considered.

13.6.2 Mechanical Components HVACR ductwork shall meet the requirements of Section 13.6.6. Piping systems shall meet the requirements of Section 13.6.7. Boilers and vessels shall meet the requirements of Section 13.6.10. Elevators shall meet the requirements of Section 13.6.11. All other mechanical components shall meet the requirements of Section 13.6.13. Mechanical components with I_p greater than 1.0 shall be designed for the seismic forces and relative displacements defined in Sections 13.3.1 and 13.3.2 and shall satisfy the following additional requirements:

1. Provision shall be made to eliminate seismic impact for components vulnerable to impact, for components constructed of nonductile materials, and in cases where material ductility will be reduced because of service conditions (e.g., low-temperature applications).
2. The possibility of loads imposed on components by attached utility or service lines, caused by differential movement of support points on separate structures, shall be evaluated.
3. Where piping or HVACR ductwork components are attached to structures that could displace relative to one another, and for isolated structures where such components cross the isolation interface, the components shall be designed to accommodate the seismic relative displacements defined in Section 13.3.2.

13.6.2.1 HVACR Equipment HVACR equipment that has been qualified in accordance with the requirements of Chapters 1 through 10 of ANSI/AHRI Standard 1270 (I-P) or ANSI/AHRI Standard 1271 (SI) shall be deemed to meet the seismic qualification requirements of Section 13.2.3, provided all of the following requirements are met:

(a) Active and/or energized components shall be seismically certified exclusively through shake table testing or experience data.
(b) The horizontal seismic design force, F_p, considered in the certification of non-active components through analysis shall be based on the procedures in Section 13.3.1 using $\left[\frac{C_{AR}}{R_{po}}\right]$ = 2.5. The value of R_μ shall be taken as 1.3 for components located above the grade plane.
(c) Capacity of non-active components used in seismic certification by analysis shall be based on the provisions of ASCE 7.
(d) Rugged components shall conform to the definition in Chapter 11.

EXCEPTION: If the period of the component, T_p, is less than or equal to 0.06 seconds, $\left[\frac{C_{AR}}{R_{po}}\right]$ may be taken as 1.0.

13.6.3 Electrical Components Conduit, cable trays, and raceways shall meet the requirements of Section 13.6.5. Utility and service lines shall meet the requirements of Section 13.6.9. Other electrical components shall meet the requirements of Section 13.6.13. All electrical components with I_p greater than 1.0 shall be designed for the seismic forces and relative displacements defined in Sections 13.3.1 and 13.3.2 and shall satisfy the following additional requirements:

1. Provision shall be made to eliminate seismic impact between components.
2. Loads imposed on the components by attached utility or service lines that are attached to separate structures shall be evaluated.
3. Batteries on racks shall have wraparound restraints to ensure that the batteries do not fall from the racks. Spacers shall be used between restraints and cells to prevent damage to cases. Racks shall be evaluated for sufficient lateral load capacity.
4. Internal coils of dry-type transformers shall be positively attached to their supporting substructure within the transformer enclosure.

@seismicisolation

5. Electrical control panels, computer equipment, and other items with slide-out components shall have a latching mechanism to hold the components in place.
6. Electrical cabinet design shall comply with the applicable National Electrical Manufacturers Association (NEMA) standards. Cutouts in the lower shear panel that have not been made by the manufacturer and that significantly reduce the strength of the cabinet shall be specifically evaluated.
7. The attachments for additional external items weighing more than 100 lb (445 N) shall be specifically evaluated if not provided by the manufacturer.
8. Where conduit, cable trays, or similar electrical distribution components are attached to structures that could displace relative to one another, and for isolated structures where such components cross the isolation interface, the components shall be designed to accommodate the seismic relative displacements defined in Section 13.3.2.

13.6.4 Component Supports Mechanical and electrical component supports (including those with $I_p = 1.0$) and the means by which they are attached to the component shall be designed for the forces and displacements determined in Sections 13.3.1 and 13.3.2. Such supports include structural members, braces, frames, skirts, legs, saddles, pedestals, cables, guys, stays, snubbers, tethers, and elements forged or cast as a part of the mechanical or electrical component.

13.6.4.1 Design Basis If standard supports designed in accordance with nationally recognized standards such as ASME B31, NFPA 13, or MSS SP-58 are used, they shall be designed by either load rating (i.e., testing) or for the calculated seismic forces. If proprietary supports are used, load rating shall be determined by approved test standards or approved material-specific design procedures. The stiffness of the support, where appropriate, shall be designed such that the seismic load path for the component performs its intended function.

13.6.4.2 Design for Relative Displacement Component supports shall be designed to accommodate the seismic relative displacements between points of support determined in accordance with Section 13.3.2.

13.6.4.3 Support Attachment to Component The means by which supports are attached to the component, except where integral (i.e., cast or forged), shall be designed to accommodate both the forces and displacements determined in accordance with Sections 13.3.1 and 13.3.2. If $I_p = 1.5$ for the component, the local region of the support attachment point to the component shall be evaluated for the effect of the load transfer on the component wall.

13.6.4.4 Material Detailing Requirements The materials comprising supports and the means of attachment to the component shall be constructed of materials suitable for the application, including the effects of service conditions, for example low-temperature applications. Materials shall be in conformance with a nationally recognized standard.

13.6.4.5 Additional Requirements The following additional requirements shall apply to mechanical and electrical component supports:

1. Seismic supports shall be constructed so that support engagement is maintained.
2. Reinforcement (e.g., stiffeners or Belleville washers) shall be provided at bolted connections through sheet metal equipment housings as required to transfer the equipment seismic loads specified in this section from the equipment to the structure. Where equipment has been certified per Section 13.2.3, 13.2.6, or 13.2.7, anchor bolts or other fasteners and associated hardware as included in the certification shall be installed in conformance with the manufacturer's instructions. For those cases where no certification exists or where instructions for such reinforcement are not provided, reinforcement methods shall be as specified by a registered design professional or as approved by the Authority Having Jurisdiction.
3. Where weak-axis bending of cold-formed steel supports is relied on for the seismic load path, such supports shall be specifically evaluated.
4. Components mounted on vibration isolators shall have a bumper restraint or snubber in each horizontal direction, and vertical restraints shall be provided where required to resist overturning. Isolator housings and restraints shall be constructed of ductile materials. (See additional design force requirements in note *a* to Table 13.6-1.) A viscoelastic pad or similar material of appropriate thickness shall be used between the bumper and components to limit the impact load.

13.6.4.6 Equipment Support Structures and Platforms Equipment support structures and platforms shall be designed in accordance with this section. The horizontal seismic design force, F_p, shall be determined in accordance with Section 13.3.1, using the design coefficients listed in Table 13.6-1. The SFRS for equipment support structures and platforms shall conform to one of the types indicated in Table 12.2-1 or 15.4-1. The SFRS used shall be in accordance with the structural system limitations noted in the tables. The selected SFRS shall be designed and detailed in accordance with the specific requirements for the system as set forth in the applicable reference documents listed in Table 12.2-1 or 15.4-1 and the additional requirements set forth in Chapter 14.

EXCEPTION: Equipment support structures and platforms designed using the coefficients for Other Systems in Table 13.6-1, under Equipment Supports, and which also conform to the requirements of relevant material standards, need not conform to one of the types indicated in Table 12.2-1 or Table 15.4-1.

Equipment support structures or platforms that are supported by a building or nonbuilding structure are permitted to be designed using $C_{AR} = 1$, $R_{po} = 1.5$, and $\Omega_{0p} = 2.0$ if the ratio $T_p/T_a < 0.2$, or if $T_p \leq 0.06$ s. The value of T_p for the equipment support structure or platform shall include consideration of the mass and stiffness of the components being supported.

13.6.4.7 Distribution System Supports Distribution system supports are assigned a component resonance ductility factor from Table 13.6-1, based on the type of support system.

Vertical and lateral supports for distribution systems, including trapeze assemblies, shall be designed for seismic forces and seismic relative displacements as required in Section 13.3, except as noted in Sections 13.6.5, 13.6.6, and 13.6.7. Distribution systems shall be braced to resist vertical, transverse, and longitudinal seismic loads. Seismic loads for distribution system supports and trapeze assemblies shall be based on the weight of the distribution system tributary to the supports, including fittings and in-line components.

13.6.5 Distribution Systems: Conduit, Cable Tray, and Raceways Cable trays and raceways shall be designed for seismic forces and seismic relative displacements as required

@seismicisolation

in Section 13.3. Conduit greater than 2.5 in. (64 mm) trade size and attached to panels, cabinets, or other equipment subject to seismic relative displacement, D_{pI}, shall be provided with flexible connections or designed for seismic forces and seismic relative displacements as required in Section 13.3.

EXCEPTIONS:

1. Design for the seismic forces and relative displacements of Section 13.3 shall not be required for raceways with $I_p = 1.0$ where flexible connections or other assemblies are provided between the cable tray or raceway and associated components to accommodate the relative displacement, where the cable tray or raceway is positively attached to the structure, and where one of the following apply:
   (a) Trapeze assemblies are used with 0.375 in. (10 mm) diameter rod hangers not exceeding 12 in. (305 mm) in length from the conduit, cable tray, or raceway support point to the connection at the supporting structure to support raceways, and the total weight supported by any single trapeze is 100 lb (445 N) or less; or
   (b) Trapeze assemblies with 0.5 in. (13 mm) diameter rod hangers not exceeding 12 in. (305 mm) in length from the conduit, cable tray, or raceway support point to the connection at the supporting structure are used to support the cable tray or raceway, and the total weight supported by any single trapeze is 200 lb (890 N) or less; or
   (c) Trapeze assemblies with 0.5 in. (13 mm) diameter rod hangers not exceeding 24 in. (610 mm) in length from the conduit, cable tray, or raceway support point to the connection at the supporting structure are used to support the cable tray or raceway, and the total weight supported by any single trapeze is 100 lb (445 N) or less; or
   (d) The conduit, cable tray, or raceway is supported by individual rod hangers 0.375 in. (10 mm) or 0.5 in. (13 mm) in diameter, and each hanger in the raceway run is 12 in. (305 mm) or less in length from the conduit, cable tray, or raceway support point connection to the supporting structure, and the total weight supported by any single rod is 50 lb (220 N) or less.
2. Design for the seismic forces and relative displacements of Section 13.3 shall not be required for conduit, regardless of the value of I_p, where the conduit is less than 2.5 in. (64 mm) trade size.

Design for the displacements across seismic joints shall be required for conduit, cable trays, and raceways with $I_p = 1.5$ without consideration of conduit size.

13.6.6 Distribution Systems: Duct Systems HVACR and other duct systems shall be designed for seismic forces and seismic relative displacements as required in Section 13.3.

EXCEPTIONS: The following exceptions pertain to ducts not designed to carry toxic, highly toxic, or flammable gases or not used for smoke control.

1. Design for the seismic forces and relative displacements of Section 13.3 shall not be required for duct systems with $I_p = 1.0$ where flexible connections or other assemblies are provided to accommodate the relative displacement between the duct system and associated components, the duct system is positively attached to the structure, and where one of the following apply:
   (a) Trapeze assemblies with 0.375 in. (10 mm) diameter rod hangers not exceeding 12 in. (305 mm) in length from the duct support point to the connection at the supporting structure are used to support the duct, and the total weight supported by any single trapeze is 100 lb (445 N) or less; or
   (b) Trapeze assemblies with 0.5 in. (13 mm) diameter rod hangers not exceeding 12 in. (305 mm) in length from the duct support point to the connection at the supporting structure are used to support the duct, and the total weight supported by any single trapeze is 200 lb (890 N) or less; or
   (c) Trapeze assemblies with 0.5 in. (13 mm) diameter rod hangers not exceeding 24 in. (610 mm) in length from the duct support point to the connection at the supporting structure are used to support the duct, and the total weight supported by any single trapeze is 100 lb (445 N) or less; or
   (d) The duct is supported by individual rod hangers 0.375 in. (10 mm) or 0.5 in. (13 mm) in diameter, and each hanger in the duct run is 12 in. (305 mm) or less in length from the duct support point to the connection at the supporting structure, and the total weight supported by any single rod is 50 lb (220 N) or less.
2. Design for the seismic forces and relative displacements of Section 13.3 shall not be required where provisions are made to avoid impact with other ducts or mechanical components or to protect the ducts in the event of such impact, the distribution system is positively attached to the structure, and HVACR ducts have a cross-sectional area of less than 6 ft^2 (0.557 m^2) and weigh 20 lb/ft (292 N/m) or less.

Components that are installed in line with the duct system and have an operating weight greater than 75 lb (334 N), such as fans, terminal units, heat exchangers, and humidifiers, shall be supported and laterally braced independent of the duct system, and such braces shall meet the force requirements of Section 13.3.1. Components that are installed in line with the duct system, have an operating weight of 75 lb (334 N) or less (such as small terminal units, valves, and dampers), and are otherwise not independently braced shall be positively attached with mechanical fasteners to rigid ducts on both sides. Appurtenances such as louvers and diffusers shall be positively attached to ducts with mechanical fasteners. Where such components are installed in a braced duct system, their weight shall be included in the design of the lateral bracing. Piping and conduit attached to in-line equipment shall be provided with adequate flexibility to accommodate the seismic relative displacements of Section 13.3.2.

13.6.7 Distribution Systems: Piping and Tubing Systems Unless otherwise noted in this section, piping and tubing systems shall be designed for the seismic forces and seismic relative displacements of Section 13.3. ASME pressure piping systems shall satisfy the requirements of Section 13.6.7.1. Fire protection sprinkler piping shall satisfy the requirements of Section 13.6.7.2. Elevator system piping shall satisfy the requirements of Section 13.6.11.

Where other applicable material standards or recognized design bases are not used, piping design including consideration of service loads shall be based on the following allowable stresses:

(a) For piping constructed with ductile materials (e.g., steel, aluminum, or copper), 90% of the minimum specified yield strength;

@seismicisolation
@seismicisolation

(b) For threaded connections in piping constructed with ductile materials, 70% of the minimum specified yield strength;
(c) For piping constructed with nonductile materials (e.g., cast iron or ceramics), 10% of the material minimum specified tensile strength; and
(d) For threaded connections in piping constructed with nonductile materials, 8% of the material minimum specified tensile strength.

Piping not detailed to accommodate the seismic relative displacements at connections to other components shall be provided with connections that have sufficient flexibility to avoid failure of the connection between the components.

Suspended components that are installed in-line and rigidly connected to and supported by the piping system, such as valves, strainers, traps, pumps, air separators, and tanks, are permitted to be considered part of the piping system for the purposes of determining the need for and sizing of lateral bracing. Where components are braced independently because of their weight but the associated piping is not braced, flexibility shall be provided as required to accommodate relative movement between the components.

13.6.7.1 ASME Pressure Piping Systems Pressure piping systems, including their supports, designed and constructed in accordance with ASME B31 shall be deemed to meet the force, displacement, and other requirements of this section. In lieu of specific force and displacement requirements in ASME B31, the force and displacement requirements of Section 13.3 shall be used. Materials meeting the toughness requirements of ASME B31 shall be considered high-deformability materials.

13.6.7.2 Fire Protection Sprinkler Piping Systems Fire protection sprinkler piping, pipe hangers, and bracing designed and constructed in accordance with NFPA 13 shall be deemed to meet the force and displacement requirements of this section. Clearances for sprinkler drops and sprigs and other equipment shall conform to 13.2.4.1. The exceptions of Section 13.6.7.3 shall not apply.

13.6.7.3 Exceptions Design for the seismic forces of Section 13.3 shall not be required for piping systems where flexible connections, expansion loops, or other assemblies are provided to accommodate the relative displacement between component and piping, where the piping system is positively attached to the structure, and where one of the following apply:

1. Trapeze assemblies are supported by 0.375 in. (10 mm) diameter rod hangers not exceeding 12 in. (305 mm) in length from the pipe support point to the connection at the supporting structure, do not support piping with I_p greater than 1.0, no single pipe exceeds the limits set forth in items 4a, 4b, or 4c below, and the total weight supported by any single trapeze is 100 lb (445 N) or less;
2. Trapeze assemblies are supported by 0.5 in. (13 mm) diameter rod hangers not exceeding 12 in. (305 mm) in length from the pipe support point to the connection at the supporting structure, do not support piping with I_p greater than 1.0, no single pipe exceeds the diameter limits set forth in items 4a, 4b, or 4c below, and the total weight supported by any single trapeze is 200 lb (890 N) or less;
3. Trapeze assemblies are supported by 0.5 in. (13 mm) diameter rod hangers not exceeding 24 in. (610 mm) in length from the pipe support point to the connection at the supporting structure, do not support piping with I_p greater than 1.0, no single pipe exceeds the diameter limits set forth in items 4a, 4b, or 4c below, and the total weight supported by any single trapeze is 100 lb (445 N) or less;
4. Piping is supported by rod hangers and provisions are made to avoid impact with other structural or nonstructural components or to protect the piping in the event of such impact; or pipes are supported by individual rod hangers 0.375 in. (10 mm) or 0.5 in. (13 mm) in diameter, where each hanger in the pipe run is 12 in. (305 mm) or less in length from the pipe support point to the connection at the supporting structure, and the total weight supported by any single hanger is 50 lb (220 N) or less. In addition, the following limitations on the size of piping shall be observed:
   (a) In structures assigned to Seismic Design Category C where I_p is greater than 1.0, the nominal pipe size shall be 2 in. (50 mm) or less.
   (b) In structures assigned to Seismic Design Category D, E, or F where I_p is greater than 1.0, the nominal pipe size shall be 1 in. (25 mm) or less.
   (c) In structures assigned to Seismic Design Category D, E, or F where $I_p = 1.0$, the nominal pipe size shall be 3 in. (80 mm) or less.
5. Pneumatic tube systems supported with trapeze assemblies using 0.375 in. (10 mm) diameter rod hangers not exceeding 12 in. (305 mm) in length from the tube support point to the connection at the supporting structure and the total weight supported by any single trapeze is 100 lb (445 N) or less.
6. Pneumatic tube systems supported by individual rod hangers 0.375 in. (10 mm) or 1.5 in. (13 mm) in diameter, and each hanger in the run is 12 in. (305 mm) or less in length from the tube support point to the connection at the supporting structure, and the total weight supported by any single rod is 50 lb (220 N) or less.

13.6.8 Distribution Systems: Trapezes with a Combination of Systems Trapezes that support a combination of distribution systems (electrical conduit, raceway, duct, piping, etc.) shall be designed using the most restrictive requirements for the supported distribution systems from Sections 13.6.5 through 13.6.7 for the aggregate weight of the supported system. If any distribution system on the trapeze is not exempted, the trapeze shall be braced.

13.6.9 Utility and Service Lines At the interface of adjacent structures or portions of the same structure that may move independently, utility lines shall be provided with adequate flexibility to accommodate the anticipated differential movement between the portions that move independently. Differential displacement shall be calculated in accordance with Section 13.3.2.

The possible interruption of utility service shall be considered in relation to designated seismic systems in Risk Category IV as defined in Table 1.5-1. Specific attention shall be given to the vulnerability of underground utilities and utility interfaces between the structure and the ground where Site Class E or F soil is present, and where the seismic coefficient S_{DS} at the underground utility or at the base of the structure is equal to or greater than 0.33.

13.6.10 Boilers and Pressure Vessels Boilers or pressure vessels designed and constructed in accordance with ASME BPVC shall be deemed to meet the force,

@seismicisolation

displacement, and other requirements of this section. In lieu of the specific force and displacement requirements in ASME BPVC, the force and displacement requirements of Sections 13.3.1 and 13.3.2 shall be used. Materials that meet the toughness requirements of ASME BPVC shall be considered high-deformability materials. Other boilers and pressure vessels designated as having $I_p = 1.5$, but not designed and constructed in accordance with the requirements of ASME BPVC, shall comply with the requirements of Section 13.6.13.

13.6.11 Elevator and Escalator Design Requirements Elevators and escalators designed in accordance with the seismic requirements of ASME A17.1 shall be deemed to meet the seismic force requirements of this section, except as modified in the following text. The exceptions of Section 13.6.7.3 shall not apply to elevator piping.

13.6.11.1 Escalators, Elevators, and Hoistway Structural Systems Escalators, elevators, and hoistway structural systems shall be designed to meet the force and displacement requirements of Sections 13.3.1 and 13.3.2.

13.6.11.2 Elevator Equipment and Controller Supports and Attachments Elevator equipment and controller supports and attachments shall be designed to meet the force and displacement requirements of Sections 13.3.1 and 13.3.2.

13.6.11.3 Seismic Controls for Elevators Elevators operating with a speed of 150 ft/min (46 m/min) or greater shall be provided with seismic switches. Seismic switches shall provide an electric signal indicating that structural motions are of such a magnitude that the operation of the elevators may be impaired. Seismic switches in accordance with Section 8.4.10.1.2 of ASME A17.1 shall be deemed to meet the requirements of this section.

EXCEPTION: In cases where seismic switches cannot be located near a column in accordance with ASME A17.1, they shall have two horizontal axes of sensitivity and have a trigger level set to 20% of the acceleration of gravity where located at or near the base of the structure and 50% of the acceleration of gravity in all other locations.

On activation of the seismic switch, elevator operations shall conform to requirements of ASME A17.1, *except* as noted in the following text.

In facilities where the loss of the use of an elevator is a life-safety issue, the elevator shall only be used after the seismic switch has triggered, provided that

1. The elevator shall operate no faster than the service speed, and
2. Before the elevator is occupied, it is operated from top to bottom and back to top to verify that it is operable.

13.6.11.4 Retainer Plates Retainer plates are required at the top and bottom of the car and counterweight.

13.6.12 Rooftop Solar Panels Rooftop solar panels and their attachments shall be designed for the forces and displacements determined in Section 13.3.

EXCEPTION: Ballasted solar panels without positive direct attachment to the roof structure are permitted on Risk Categories I, II, and III structures six stories or fewer in height and having a maximum roof slope equal to or less than 1 in 20, provided that they comply with the following.

1. The height of the center of mass of any panel above the roof surface is less than half the least spacing in plan of the panel supports, but in no case greater than 3 ft (0.9 m).
2. Each panel or array of panels is designed to accommodate without impact, instability, or loss of support a seismic displacement, δ_{mpv}, of any panel relative to any roof edge or offset and any other curb or obstruction to sliding on the roof surface where δ_{mpv} is determined in accordance with Equation (13.6-1), but is not taken as less than 2 ft (0.6 m):

$$\delta_{mpv} = 5I_e(S_{DS} - 0.4)^2 \text{[ft]} \quad (13.6\text{-}1)$$

$$\delta_{mpv} = 1.5I_e(S_{DS} - 0.4)^2 \text{[m]} \quad (13.6\text{-}1.\text{SI})$$

   Any portion of an unattached array of panels that is not interconnected as specified in Item 3, shall be provided with a minimum separation between adjacent unattached panels of not less than $0.5\delta_{mpv}$. Signage or roof markings (e.g., yellow stripes) shall be provided to delineate the area around the panel that must be kept free of obstructions. Alternatively, δ_{mpv} may be determined by shake table testing or nonlinear response history analysis, whereby the value of δ_{mpv} shall not be taken as less than 80% of the value given by Equation (13.6-1) unless independent peer review is conducted in accordance with Section 1.3.1.3.4.
3. Each array of panels is interconnected as an integral unit to form a continuous load path such that the members and connections have the design strength to resist a horizontal force of $0.2S_{DS}W_{pi}$ in tension and compression considering any eccentricities, across any section cut by a vertical plane, where W_{pi} is the weight of the smaller of the two portions. The solar panels shall not be considered as part of the load path that resists the interconnection force unless the panels have been evaluated or tested for such loading.
4. Panel framing and supports are designed for a seismic force path from the center of mass of each component to locations of friction resistance equal to the lesser of F_p from Section 13.3.1 and $0.6W_p$, where W_p is the weight of each component.
5. All electrical cables leading from a panel to another panel or to another roof object are designed to accommodate, without rupture or distress, differential movements between cable connection points of $1.0\delta_{mpv}$, with consideration given to torsional movement of the panel and its possible impingement on the electrical cables.
6. All edges and offsets of roof surfaces on which panels are placed are bounded by a curb or parapet not less than 12 in. (305 mm) in height and designed to resist a concentrated load applied at the probable points of impact between the curb or parapet and the panel of not less than $0.2S_{DS}$ times the weight of the panel. Alternatively, a panel may be placed so that all parts of the panel are a minimum of $2.0\delta_{mpv}$, but not less than 4 ft (1.22 m), from any roof edge or offset.
7. Where justified by testing and analysis, the maximum roof slope for structures assigned to Seismic Design Categories C and D shall be permitted to be 1 in 12 provided that independent peer review is conducted in accordance with Section 1.3.1.3.4.

13.6.13 Other Mechanical and Electrical Components Mechanical and electrical components, including conveyor

@seismicisolation

systems, not designed and constructed in accordance with the reference documents in Chapter 23 shall meet the following:

1. Components and their supports and attachments shall comply with the requirements of Sections 13.4, 13.6.2, 13.6.3, and 13.6.4.
2. For mechanical components with hazardous substances and assigned a component Importance Factor, I_p, of 1.5 in accordance with Section 13.1.3, and for boilers and pressure vessels not designed in accordance with ASME BPVC, the design strength for seismic loads in combination with other service loads and appropriate environmental effects shall be based on the following material properties:
   (a) For mechanical components constructed with ductile materials (e.g., steel, aluminum, or copper), 90% of the minimum specified yield strength;
   (b) For threaded connections in components constructed with ductile materials, 70% of the minimum specified yield strength;
   (c) For mechanical components constructed with nonductile materials (e.g., plastic, cast iron, or ceramics), 10% of the material minimum specified tensile strength; and
   (d) For threaded connections in components constructed with nonductile materials, 8% of the material minimum specified tensile strength.

13.7 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

See Chapter 23 for the list of consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

CHAPTER 14
MATERIAL-SPECIFIC SEISMIC DESIGN AND DETAILING REQUIREMENTS

14.0 SCOPE

Structural elements, including foundation elements, shall conform to the material design and detailing requirements set forth in this chapter or as otherwise specified for nonbuilding structures in Tables 15.4-1 and 15.4-2.

14.1 STEEL

Structures, including foundations, constructed of steel to resist seismic loads shall be designed and detailed in accordance with this standard including the reference documents and additional requirements provided in this section.

14.1.1 Reference Documents The design, construction, and quality of steel members that resist seismic forces shall conform to the applicable requirements, as amended herein, of ANSI/AISC 341, ANSI/AISC 360, ANSI/AISI S100, ANSI/AISI S230, ANSI/AISI S240, ANSI/AISI S310, ANSI/AISI S400, ANSI/SDI-QA/QC, ANSI/SDI-SD, ANSI/SJI-100, ANSI/SJI-200, ASCE 8, and ASCE 19.

14.1.2 Structural Steel

14.1.2.1 General The design of structural steel for buildings and structures shall be in accordance with ANSI/AISC 360. Where required, the seismic design of structural steel structures shall be in accordance with the additional provisions of Section 14.1.2.2.

14.1.2.2 Seismic Requirements for Structural Steel Structures The design of structural steel structures to resist seismic forces shall be in accordance with the provisions of Section 14.1.2.2.1 or 14.1.2.2.2, as applicable.

14.1.2.2.1 Seismic Design Categories B and C. Structural steel structures assigned to Seismic Design Category B or C shall be of any construction permitted by the applicable reference documents in Section 14.1.1. Where a response modification coefficient, R, is used in accordance with Table 12.2-1 for the design of structural steel structures assigned to Seismic Design Category B or C, the structures shall be designed and detailed in accordance with the requirements of AISC 341.

EXCEPTION: The response modification coefficient, R, designated for "steel systems not specifically detailed for seismic resistance, excluding cantilever column systems" in Table 12.2-1 shall be permitted for systems designed and detailed in accordance with AISC 360 and need not be designed and detailed in accordance with AISC 341.

14.1.2.2.2 Seismic Design Categories D through F. Structural steel structures assigned to Seismic Design Category D, E, or F shall be designed and detailed in accordance with AISC 341, except as permitted in Table 15.4-1.

14.1.3 Cold-Formed Steel

14.1.3.1 General The design of cold-formed carbon or low-alloy steel structural members shall be in accordance with the requirements of AISI S100, and the design of cold-formed stainless steel structural members shall be in accordance with the requirements of ASCE 8. Where required, the seismic design of cold-formed steel structures shall be in accordance with the additional provisions of Section 14.1.3.2.

14.1.3.2 Seismic Requirements for Cold-Formed Steel Structures Where a response modification coefficient, R, in accordance with Table 12.2-1, is used for the design of cold-formed steel structures, the structures shall be designed and detailed in accordance with the requirements of AISI S100, ASCE 8, and AISI S400, as applicable.

14.1.4 Cold-Formed Steel Light-Frame Construction

14.1.4.1 General Cold-formed steel light-frame construction shall be designed in accordance with AISI S240. Where required, the seismic design of cold-formed steel light-frame construction shall be in accordance with the additional provisions of Section 14.1.4.2.

14.1.4.2 Seismic Requirements for Cold-Formed Steel Light-Frame Construction The design of cold-formed steel light-frame construction to resist seismic forces shall be in accordance with the provisions of Section 14.1.4.2.1 or 14.1.4.2.2, as applicable.

14.1.4.2.1 Seismic Design Categories B and C. Where a response modification coefficient, R, in accordance with Table 12.2-1 is used for the design of cold-formed steel light-frame construction assigned to Seismic Design Category B or C, the structures shall be designed and detailed in accordance with the requirements of AISI S400.

EXCEPTION: The response modification coefficient, R, designated for "steel systems not specifically detailed for seismic resistance, excluding cantilever column systems" in Table 12.2-1 shall be permitted for systems designed and detailed in accordance with AISI S240 and need not be designed and detailed in accordance with AISI S400.

14.1.4.2.2 Seismic Design Categories D through F. Cold-formed steel light-frame construction structures assigned to Seismic Design Category D, E, or F shall be designed and detailed in accordance with AISI S400.

14.1.4.3 Prescriptive Cold-Formed Steel Light-Frame Construction Cold-formed steel light-frame construction for one- and two-family dwellings is permitted to be designed and constructed in accordance with the requirements of AISI S230 subject to the limitations therein.

@seismicisolation

14.1.5 Cold-Formed Steel Deck Diaphragms Cold-formed steel deck diaphragms shall be designed in accordance with the requirements of AISI S100, AISI S240, SDI-SD, or ASCE 8, as applicable. Nominal strengths shall be determined in accordance with AISI S310. The required strength of diaphragms, including bracing members that form part of the diaphragm, shall be determined in accordance with Section 12.10. Where required by this standard, special seismic detailing requirements shall be in accordance with AISI S400. Special inspections and qualification of welding special inspectors for cold-formed steel floor and roof deck shall be in accordance with the quality assurance inspection requirements of SDI-QA/QC.

14.1.6 Concrete-Filled Steel Deck Diaphragms Concrete-filled steel deck diaphragms shall be of any construction permitted by the applicable reference documents in Section 14.1.1. Where a Diaphragm Design Force Reduction Factor, R_s, in accordance with Table 12.10-1, is used for design, the concrete-filled steel deck diaphragm and shear transfer to structural steel members shall be designed and detailed in accordance with the requirements of AISC 341.

14.1.7 Open Web Steel Joists and Joist Girders The design, manufacture, and use of open web steel joists and joist girders shall be in accordance with SJI-100 and SJI-200, as applicable.

14.1.8 Steel Cables The design strength of steel cables serving as main structural load carrying members shall be determined by the requirements of ASCE 19.

14.1.9 Additional Detailing Requirements for Steel Piles in Seismic Design Categories D through F In addition to the foundation requirements set forth in Sections 12.1.5 and 12.13, design and detailing of H-piles shall conform to the requirements of AISC 341, and the connection between the pile cap and steel piles or unfilled steel pipe piles in structures assigned to Seismic Design Category D, E, or F shall be designed for a tensile force not less than 10% of the pile compression capacity.

EXCEPTION: Connection tensile capacity need not exceed the strength required to resist the seismic load effects including overstrength of Section 12.4.3 or 12.14.3.2. Connections need not be provided where the foundation or supported structure does not rely on the tensile capacity of the piles for stability under the design seismic forces.

14.2 CONCRETE

Structures, including foundations, constructed of concrete to resist seismic loads shall be designed and detailed in accordance with this standard, including the reference documents and additional requirements provided in this section.

14.2.1 Reference Documents The quality and testing of concrete materials and the design and construction of structural concrete members that resist seismic forces shall conform to the requirements of ACI 318, except as modified in Section 14.2.2.

14.2.2 Modifications to ACI 318 The text of ACI 318 shall be modified as indicated in Sections 14.2.2.1 through 14.2.2.7. Italics are used for text within Sections 14.2.2.1 through 14.2.2.7 to indicate requirements that differ from ACI 318.

14.2.2.1 Definitions Add the following definitions to ACI 318, Section 2.3.

Cast-In-Place Concrete Equivalent Precast Diaphragm: A cast-in-place noncomposite topping slab diaphragm, as defined in ACI 318, Section 18.12.5, or a diaphragm constructed with precast concrete components that uses closure strips between precast components with detailing that meets the requirements of ACI 318 for the seismic design category of the structure.

Detailed Plain Concrete Structural Wall: A wall complying with the requirements of ACI 318, Chapter 14.

Ordinary Precast Structural Wall: A precast wall complying with the requirements of ACI 318 excluding Chapters 14, 18, and 27.

Precast Concrete Diaphragm: A diaphragm constructed with precast concrete components, with or without a cast-in-place topping, that includes the use of discrete connectors or joint reinforcement to transmit diaphragm forces.

14.2.2.2 ACI 318, Section 10.7.6 Modify Section 10.7.6 by revising Section 10.7.6.1.5 to read as follows:

10.7.6.1.5 *In structures assigned to Seismic Design Categories C, D, E, or F, the ties or hoops shall have a hook on each free end that complies with Section 25.3.4.*

14.2.2.3 Scope Modify ACI 318, Section 18.2.1.2, to read as follows:

18.2.1.2 *All members shall satisfy requirements of Chapters 1 to 17 and 19 to 26. Structures assigned to SDC B, C, D, E, or F also shall satisfy Sections 18.2.1.3 through 18.2.1.7, as applicable, except as modified by the requirements of Chapters 14 and 15 of ASCE 7. Where ACI 318, Chapter 18, conflicts with other ACI 318 chapters, Chapter 18 shall govern.*

14.2.2.4 Intermediate Precast Structural Walls Modify ACI 318, Section 18.5, by renumbering Sections 18.5.2.2 and 18.5.2.3 to Sections 18.5.2.3 and 18.5.2.4, respectively, and adding a new Section 18.5.2.2 to read as follows:

18.5.2.2 *Connections that are designed to yield shall be capable of maintaining 80% of their design strength at the deformation induced by design displacement or shall use type 2 mechanical splices.*

18.5.2.3 *For elements of the connection that are not designed to yield, the required strength shall be based on $1.5S_y$ of the yielding portion of the connection.*

18.5.2.4 *In structures assigned to SDC D, E, or F, wall piers shall be designed in accordance with 18.10.8 or 18.14.*

14.2.2.5 Special Precast Structural Walls Modify ACI 318, Section 18.11.2.1, to read as follows:

18.11.2.1 *Special structural walls constructed using precast concrete shall satisfy 18.10 in addition to 18.5.2 as modified by Section 14.2.2 of ASCE 7, except 18.10.2.4 shall not apply for precast walls where deformation demands are concentrated at the panel joints.*

14.2.2.6 Foundations Modify ACI 318, Section 18.13.1.1, to read as follows:

18.13.1.1 *Section 18.13, as modified by Sections 12.1.5 or 12.13 of ASCE 7, shall apply to foundations resisting earthquake-induced forces or transferring earthquake-induced forces between structure and ground.*

14.2.2.7 Detailed Plain Concrete Shear Walls Modify ACI 318, Section 14.6, by adding a new Section 14.6.2 to read:

14.6.2 Detailed Plain Concrete Shear Walls

14.6.2.1 *Detailed plain concrete shear walls are walls conforming to the requirements for ordinary plain concrete shear walls and Section 14.6.2.2.*

14.6.2.2 *Reinforcement shall be provided as follows:*

@seismicisolation

(a) *Vertical reinforcement of at least 0.20 in^2 (129 mm^2) in cross-sectional area shall be provided continuously from support to support at each corner, at each side of each opening, and at the ends of walls. The continuous vertical bar required beside an opening is permitted to substitute for the No. 5 bar required by Section 11.7.5.1.*

(b) *Horizontal reinforcement of at least 0.20 in^2 (129 mm^2) in cross-sectional area shall be provided*:

1. *Continuously at structurally connected roof and floor levels and at the top of walls;*
2. *At the bottom of load-bearing walls or in the top of foundations where doweled to the wall; and*
3. *At a maximum spacing of 120 in. (3,048 mm).*

Reinforcement at the top and bottom of openings, where used in determining the maximum spacing specified in Item 3 in the preceding text, shall be continuous in the wall.

14.3 COMPOSITE STEEL AND CONCRETE STRUCTURES

Structures, including foundations, constructed of composite steel and concrete to resist seismic loads shall be designed and detailed in accordance with this standard, including the reference documents and additional requirements provided in this section.

14.3.1 Reference Documents The design, construction, and quality of composite steel and concrete members that resist seismic forces shall conform to the applicable requirements of AISC 341, AISC 360, and ACI 318, excluding Chapter 14.

14.3.2 General Systems of structural steel acting compositely with reinforced concrete shall be designed in accordance with AISC 360 and ACI 318, excluding Chapter 14. Where required, the seismic design of composite steel and concrete systems shall be in accordance with the additional provisions of Section 14.3.3.

14.3.3 Seismic Requirements for Composite Steel and Concrete Structures Where a response modification coefficient, *R*, in accordance with Table 12.2-1 is used for the design of systems of structural steel acting compositely with reinforced concrete, the structures shall be designed and detailed in accordance with the requirements of AISC 341.

14.3.4 Metal-Cased Concrete Piles Metal-cased concrete piles shall be designed and detailed in accordance with ACI 318.

14.4 MASONRY

Structures, including foundations, constructed of masonry to resist seismic loads shall be designed and detailed in accordance with this standard, including the references and additional requirements provided in this section.

14.4.1 Reference Documents The design, construction, and quality assurance of masonry members that resist seismic forces shall conform to the requirements of TMS 402 and TMS 602, except as modified by Section 14.4.

14.4.2 *R* Factors To qualify for the response modification coefficients, *R*, set forth in this standard, the requirements of TMS 402 and TMS 602, as amended in subsequent sections, shall be satisfied.

Special reinforced masonry shear walls designed in accordance with Section 8.3 or 9.3 of TMS 402 shall also comply with the additional requirements in Section 14.4.4 or 14.4.5.

14.4.3 Modifications to Chapter 7 of TMS 402

14.4.3.1 Separation Joints Add the following new Section 7.5.1 to TMS 402:

7.5.1 Separation Joints *Where concrete abuts structural masonry and the joint between the materials is not designed as a separation joint, the concrete shall be roughened so that the average height of aggregate exposure is 0.125 in. (3 mm) and shall be bonded to the masonry in accordance with these requirements as if it were masonry. Vertical joints not intended to act as separation joints shall be crossed by horizontal reinforcement as required by Section 5.1.1.2.*

14.4.4 Modifications to Chapter 6 of TMS 402

14.4.4.1 Reinforcement Requirements and Details

14.4.4.1.1 Reinforcing Bar Size Limitations. Modify TMS 402, Section 6.1.2, as follows.

Delete TMS 402, Section 6.1.2.1 and replace with:

6.1.2.1 Reinforcing bars used in masonry shall not be larger than No. 9 (M#29).

Delete TMS 402, Section 6.1.2.2 and replace with:

6.1.2.2 The nominal bar diameter shall not exceed one-quarter of the least clear dimension of the cell, course, or collar joint in which it is placed.

Add the following sentence to the end of TMS 402, Section 6.1.2.4:

The area of reinforcing bars placed in a cell or in a course of hollow unit construction shall not exceed 4% of the cell area.

14.4.4.1.2 Splices in Reinforcement. Add the following new Sections 6.1.6.1.1.4 and 6.1.6.1.2.1 to TMS 402:

6.1.6.1.1.4 Where $M/V_u d_v$ exceeds 1.5 and the seismic load associated with the development of the nominal shear capacity exceeds 80% of the seismic load associated with development of the nominal flexural capacity, lap splices shall not be used in plastic hinge zones of special reinforced masonry shear walls. The length of the plastic hinge zone shall be taken as at least 0.15 times the distance between the point of zero moment and the point of maximum moment.

6.1.6.1.2.1 Where $M/V_u d_v$ exceeds 1.5 and the seismic load associated with the development of the nominal shear capacity exceeds 80% of the seismic load associated with development of the nominal flexural capacity, welded splices shall not be permitted in plastic hinge zones of special reinforced walls of masonry.

14.4.5 Modifications to Chapter 9 of TMS 402

14.4.5.1 Anchoring to Masonry Add the following as the first paragraph in TMS 402, Section 9.1.6:

9.1.6 Anchor Bolts Embedded in Grout *Anchorage assemblies connecting masonry elements that are part of the seismic force-resisting system to diaphragms and chords shall be designed so that the strength of the anchor is governed by steel tensile or shear yielding. Alternatively, the anchorage assembly is permitted to be designed so that it is governed by masonry breakout or anchor pullout, provided the anchorage assembly is designed to resist not less than 2.0 times the factored forces transmitted by the assembly.*

14.4.5.2 Coupling Beams Add the following new Section 9.3.4.2.5 to TMS 402:

9.3.4.2.5 Coupling Beams. *Structural members that provide coupling between shear walls shall be designed to reach their moment or shear nominal strength before either shear wall*

@seismicisolation
@seismicisolation

reaches its moment or shear nominal strength. Analysis of coupled shear walls shall comply with accepted principles of mechanics.

The design shear strength, ϕV_n, of the coupling beams shall satisfy the following criterion:

$$\phi V_n \geq \frac{1.25(M_1 + M_2)}{L_c} + 1.4V_g$$

where

M_1, M_2 = *Nominal moment strength at the ends of the beam,*
L_c = *Length of the beam between the shear walls, and*
V_g = *Unfactored shear force caused by gravity loads.*

The calculation of the nominal flexural moment shall include the reinforcement in reinforced concrete roof and floor systems. The width of the reinforced concrete used for calculations of reinforcement shall be six times the floor or roof slab thickness.

14.4.6 Modifications to Chapter 12 of TMS 402

14.4.6.1 Corrugated Sheet Metal Anchors Add Section 12.2.2.11.1.1 to TMS 402 as follows:

12.2.2.11.1.1 *Corrugated sheet metal anchors shall not be used.*

14.5 WOOD

Structures, including foundations, constructed of wood to resist seismic loads shall be designed and detailed in accordance with this standard including the references and additional requirements provided in this section.

14.5.1 Reference Documents The quality, testing, design, and construction of members and their fastenings in wood systems that resist seismic forces shall conform to the requirements of the applicable following reference documents: AWC NDS and AWC SDPWS.

14.6 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

See Chapter 23 for the list of consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

@seismicisolation
@seismicisolation

CHAPTER 15
SEISMIC DESIGN REQUIREMENTS FOR NONBUILDING STRUCTURES

15.1 GENERAL

15.1.1 Nonbuilding Structures The provisions of this chapter shall apply to unoccupied nonbuilding structures and buildings whose primary purpose is to enclose equipment or machinery and whose occupants are engaged in maintenance or monitoring of that equipment, machinery, or their processes. Nonbuilding structures at or below the grade plane or supported by other structures shall be designed and detailed to resist the minimum lateral forces specified in this chapter. Design shall conform to the applicable requirements of other sections as modified by this section. Foundation design shall comply with the requirements of Sections 12.1.5 and 12.13, and Chapter 14.

15.1.2 Design The design of nonbuilding structures shall provide sufficient stiffness, strength, and ductility consistent with the requirements specified herein for buildings to resist the effects of seismic ground motions as represented by these design forces:

(a) Applicable strength and other design criteria shall be obtained from other portions of the seismic requirements of this standard or its reference documents.
(b) Where applicable strength and other design criteria are not contained in or referenced by the seismic requirements of this standard, such criteria shall be obtained from reference documents. Where reference documents define acceptance criteria in terms of allowable stresses as opposed to strength, the design seismic forces shall be obtained from this section and used in combination with other loads as specified in Section 2.4 of this standard and used directly with allowable stresses specified in the reference documents. Detailing shall be in accordance with the reference documents.

15.1.3 Structural Analysis Procedure Selection Structural analysis procedures for nonbuilding structures that are similar to buildings shall be selected in accordance with Section 12.6. Nonbuilding structures that are not similar to buildings shall be designed using the equivalent lateral force procedure in accordance with Section 12.8, the linear dynamic analysis procedures in accordance with Section 12.9, the nonlinear response history analysis procedure in accordance with Chapter 16, or the procedure prescribed in the specific reference document.

15.1.4 Nonbuilding Structures Sensitive to Vertical Ground Motions Tanks, vessels, hanging structures, and nonbuilding structures incorporating horizontal cantilevers shall use Section 11.9 to determine the vertical seismic design ground motion to be applied to the design of the nonbuilding structure. For these structures, the design forces in members and connections shall be determined by modal analysis performed in accordance with Section 12.9 or response history analysis performed in accordance with Chapter 12 or 16, except that the vertical ground motion component shall be included in the analysis using the spectra defined in Section 11.9. Alternatively, the equivalent static procedures of Section 12.8 and Section 15.4 are permitted to be used to determine the seismic design force with the vertical component motions. For tanks and vessels, vertical ground motions shall be applied as required by Section 15.7.2, Item (c). For hanging structures and nonbuilding structures incorporating horizontal cantilevers, the design vertical response spectral acceleration, S_{av}, shall be taken as the peak value from the response spectrum of Section 11.9. Alternatively, the design vertical response spectral acceleration, S_{av}, is permitted to be determined using the provisions of Section 11.9, with the vertical period of the structure determined by rational analysis. Horizontal seismic effects shall be combined with vertical seismic effects using the direction of loading criteria specified in Section 15.1.4.1 for hanging structures and structures incorporating horizontal cantilevers. The response modification factor, R, for use with vertical seismic design ground motions shall be taken as 1.0, except in the determination of hydrodynamic hoop forces in cylindrical tank walls. The determination of hydrodynamic hoop forces caused by vertical seismic design ground motions in cylindrical tank walls shall comply with the requirements of Section 15.7.2, Item (c), ii.

15.1.4.1 Direction of Loading Criteria for Nonbuilding Structures Sensitive to Vertical Ground Motions The following orthogonal load combinations of horizontal and vertical seismic load effects shall be applied to hanging structures and structures incorporating horizontal cantilevers.

15.1.4.1.1 Strength The directions of application of seismic forces used in the strength design of structure elements shall be those that produce the most critical load effects. This requirement is deemed satisfied if the structure elements are designed to the more stringent demands of the following load directions:

1. 100% of the forces for one horizontal direction plus 30% of the forces for the perpendicular horizontal direction plus 30% of the forces for the vertical direction. The combination requiring the maximum component strength shall be used.
2. 100% of the forces for the vertical direction plus 30% of the forces for a horizontal direction plus 30% of the forces for the perpendicular horizontal direction. The combination requiring the maximum component strength shall be used.

15.1.4.1.2 Overturning and Stability The directions of application of seismic forces used in the evaluation of overturning stability and sliding of the structure shall be those that produce

@seismicisolation
@seismicisolation

the most critical load effects. This requirement is deemed satisfied if the structures and their foundations are evaluated for overturning stability and sliding using the following load directions:

1. 100% of the forces for one horizontal direction plus 30% of the forces for the perpendicular horizontal direction plus 30% of the forces for the vertical direction. The combination requiring the maximum component strength shall be used.

15.2 NONBUILDING STRUCTURES CONNECTED BY NONSTRUCTURAL COMPONENTS TO OTHER ADJACENT STRUCTURES

15.2.1 General Requirements For nonbuilding structures connected by nonstructural components to other adjacent structures, an analysis combining the structural characteristics of the nonbuilding structure, the adjacent structure, and the connecting nonstructural components in accordance with the requirements of Chapter 12 or Section 15.5, as appropriate, shall be performed to determine the seismic forces.

EXCEPTIONS: Regular nonbuilding structures connected to regular adjacent structures are permitted to be designed independently, with the tributary weight of the nonstructural components considered in the determination of the effective seismic weight, W, for any of the following conditions:

(a) The ratio of the fundamental period of the nonbuilding structure to that of the adjacent connected structure in the direction of motion is greater than 0.9 and less than 1.1.
(b) The ratio of the fundamental period of the nonbuilding structure to that of the adjacent structure in the direction of motion is greater than 0.8 and less than 1.2 and the ratio of the effective seismic weight of the nonbuilding structure and the adjacent structure is greater than 0.8 and less than 1.2.
(c) The ratio of the stiffness of the connecting nonstructural components to that of the nonbuilding structure in the direction of motion and the ratio of the stiffness of the connecting nonstructural components to that of the adjacent structure in the direction of motion are both less than 0.2.

15.2.2 Nonstructural Components Spanning between Nonbuilding Structures Nonstructural components spanning between nonbuilding structures shall comply with all applicable requirements of Chapter 13. Design and detailing for relative displacement between structures shall be in accordance with Section 13.3.2.2.

15.3 NONBUILDING STRUCTURES SUPPORTED BY OTHER STRUCTURES

Where nonbuilding structures identified in Table 15.4-2 are supported by other structures and nonbuilding structures are not part of the primary seismic force-resisting system, one of the following methods shall be used.

15.3.1 Supported Nonbuilding Structures with Less Than 20% of Combined Weight For the condition where the weight of the supported nonbuilding structure is less than 20% of the combined effective seismic weights of the nonbuilding structure and supporting structure, the design seismic forces of the nonbuilding structure shall be determined in accordance with Chapter 13, where the values of C_{AR} and R_{po} shall be determined in accordance with Section 13.1.6. The supporting structure shall be designed in accordance with the requirements of Chapter 12 or Section 15.5, as appropriate, with the weight of the nonbuilding structure considered in the determination of the effective seismic weight, W.

EXCEPTIONS:

(a) Where the ratio of the fundamental period of the nonbuilding structure to that of the supporting structure (including the lumped weight of the nonbuilding structure) is greater than 2.0, the supporting structure is permitted to be designed in accordance with the requirements of Chapter 12 or Section 15.5, as appropriate, with the nonbuilding structure modeled as attached to a rigid base.
(b) Where the ratio of the fundamental period of the nonbuilding structure to that of the supporting structure (including the lumped weight of the nonbuilding structure) is less than 0.5, the supporting structure is permitted to be designed in accordance with the requirements of Chapter 12 or Section 15.5, as appropriate, with the weight of the nonbuilding structure considered in the determination of the effective seismic weight, W. The supported nonbuilding structure shall follow the requirements of Section 15.3.1.

15.3.2 Supported Nonbuilding Structures with Greater Than or Equal to 20% of Combined Weight For the condition where the weight of the supported nonbuilding structure is equal to or greater than 20% of the combined effective seismic weight of the nonbuilding structure and supporting structure, an analysis combining the structural characteristics of both the nonbuilding structure and the supporting structures shall be performed to determine the seismic design forces.

The combined structure shall be designed in accordance with Section 15.5, with the R value of the combined system taken as the lesser of the R values of the nonbuilding structure or the supporting structure. The nonbuilding structure and attachments shall be designed for the forces determined for the nonbuilding structure in the combined analysis.

EXCEPTIONS:

(a) Where the ratio of the fundamental period of the nonbuilding structure to that of the supporting structure (including the lumped weight of the nonbuilding structure) is greater than 2.0, the supporting structure is permitted to be designed in accordance with the requirements of Chapter 12 or Section 15.5, as appropriate, with the nonbuilding structure modeled as attached to a rigid base.
(b) Where the ratio of the fundamental period of the nonbuilding structure to that of the supporting structure (including the lumped weight of the nonbuilding structure) is less than 0.5, the supporting structure is permitted to be designed in accordance with the requirements of Chapter 12 or Section 15.5, as appropriate, with the weight of the nonbuilding structure considered in the determination of the effective seismic weight, W. The supported nonbuilding structure shall follow the requirements of Section 15.3.1.

@seismicisolation
@seismicisolation

15.3.3 Nonstructural Components Supported by Nonbuilding Structures Nonstructural components supported by nonbuilding structures shall be designed in accordance with Chapter 13 of this standard.

15.4 STRUCTURAL DESIGN REQUIREMENTS

15.4.1 Design Basis Nonbuilding structures that have specific seismic design criteria established in reference documents shall be designed using the standards as amended herein. Where reference documents are not cited herein, nonbuilding structures shall be designed in compliance with Sections 15.5 and 15.6 to resist minimum seismic lateral forces that are not less than the requirements of Section 12.8, with the following additions and exceptions.

1. The seismic force-resisting system shall be selected as follows:
   (a) For nonbuilding structures similar to buildings, a system shall be selected from among the types indicated in Table 12.2-1 or Table 15.4-1 subject to the system limitations and limits on structural height, h_n, based on the seismic design category indicated in the table. The appropriate values of R, Ω_0, and C_d indicated in the selected table shall be used in determining the base shear, element design forces, and design story drift as indicated in this standard. Design and detailing requirements shall comply with the sections referenced in the selected table.
   (b) For nonbuilding structures not similar to buildings, a system shall be selected from among the types

Table 15.4-1. Seismic Coefficients for Nonbuilding Structures Similar to Buildings.

					Structural System and Structural Height, h_n, Limits (ft)[a]				
					Seismic Design Category				
Nonbuilding Structure Type	Detailing Requirements	R	Ω_0	C_d	B	C	D[b]	E[b]	F[c]

Special reinforced concrete moment frames[g]	ACI 318, including Ch. 18	8	3	5.5	NL	NL	NL	NL	NL
Steel intermediate moment frames:	AISC 341	4.5	3	4	NL	NL	35[h,i]	NP[h,i]	NP[h,i]
With permitted height increase	AISC 341	2.5	2	2.5	NL	NL	160	160	100
With unlimited height	AISC 341	1.5	1	1.5	NL	NL	NL	NL	NL
Intermediate reinforced concrete moment frames:	ACI 318, including Ch. 18	5	3	4.5	NL	NL	NP	NP	NP
With permitted height increase	ACI 318, including Ch. 18	3	2	2.5	NL	NL	50	50	50
With unlimited height	ACI 318, including Ch. 18	0.8	1	1	NL	NL	NL	NL	NL
Steel ordinary moment frames:	AISC 341	3.5	3	3	NL	NL	NP[h,i]	NP[h,i]	NP[h,i]
With permitted height increase	AISC 341	2.5	2	2.5	NL	NL	100	100	NP[h,i]
With unlimited height	AISC 360	1	1	1	NL	NL	NL	NL	NL
Ordinary reinforced concrete moment frames:	ACI 318, excluding Ch. 18	3	3	2.5	NL	NP	NP	NP	NP
With permitted height increase	ACI 318, excluding Ch. 18	0.8	1	1	NL	NL	50	50	50

[a] NL = no limit; NP = not permitted.
[b] See Section 12.2.5.4 for a description of seismic force-resisting systems limited to structures with a structural height, h_n, of 240 ft (73.2 m) or less.
[c] See Section 12.2.5.4 for seismic force-resisting systems limited to structures with a structural height, h_n, of 160 ft (48.8 m) or less.
[d] The column-to-base connection shall be designed to the lesser of M_n of the column or the factored moment at the base of the column for the seismic load case using the overstrength factor.
[e] Cold-formed sections that meet the requirements of AISC 341, Table D1.1, are permitted to be designed in accordance with AISC 341.
[f] Steel ordinary braced frames are permitted in pipe racks up to 65 ft (20 m).
[g] In Section 2.3 of ACI 318, the definition of "special moment frame" includes precast and cast-in-place construction.
[h] Steel ordinary moment frames and intermediate moment frames are permitted in pipe racks up to 65 ft (20 m) where the moment joints of field connections are constructed of bolted end plates.
[i] Steel ordinary moment frames and intermediate moment frames are permitted in pipe racks up to 35 ft (11 m).

@seismicisolation
@seismicisolation

indicated in Table 15.4-2 subject to the system limitations and limits on structural height, h_n, based on seismic design category indicated in the table. The appropriate values of R, Ω_0, and C_d indicated in Table 15.4-2 shall be used in determining the base shear, element design forces, and design story drift as indicated in this standard. Design and detailing requirements shall comply with the sections referenced in Table 15.4-2.

2. For nonbuilding systems that have an R value provided in Table 15.4-2, the minimum specified value in Equation (12.8-5) shall be replaced by

$$C_s = 0.044 S_{DS} I_e \quad (15.4\text{-}1)$$

Table 15.4-2. Seismic Coefficients for Nonbuilding Structures Not Similar to Buildings.

					Structural System and Structural Height, h_n, Limits (ft)[a,b]				
					Seismic Design Category				
Nonbuilding Structure Type	Detailing Requirements[c]	R	Ω_0	C_d	B	C	D	E	F
Elevated tanks, vessels, bins, or hoppers:									
On symmetrically braced integral legs (not similar to buildings)	Section 15.7.10	3	2[d]	2.5	NL	NL	160	100	100

Table 15.4-2 *(Continued)*. Seismic Coefficients for Nonbuilding Structures Not Similar to Buildings.

Nonbuilding Structure Type	Detailing Requirements[c]	R	Ω_0	C_d	Structural System and Structural Height, h_n, Limits (ft)[a,b] Seismic Design Category B	C	D	E	F
Telecommunication towers:	15.6.6								
Truss: Steel		3	1.5	3	NL	NL	NL	NL	NL
Pole: Steel		1.5	1.5	1.5	NL	NL	NL	NL	NL
Wood		1.5	1.5	1.5	NL	NL	NL	NL	NL
Concrete		1.5	1.5	1.5	NL	NL	NL	NL	NL
Frame: Steel		3	1.5	1.5	NL	NL	NL	NL	NL
Wood		1.5	1.5	1.5	NL	NL	NL	NL	NL
Concrete		2	1.5	1.5	NL	NL	NL	NL	NL
Amusement structures and monuments	15.6.3	2	2	2	NL	NL	NL	NL	NL
Inverted-pendulum-type structures (except elevated tanks, vessels, bins, and hoppers)	12.2.5.3	2	2	2	NL	NL	NL	NL	NL
Ground-supported cantilever walls or fences	15.6.8	1.25	2	2.5	NL	NL	NL	NL	NL
Signs and billboards		3.0	1.75	3	NL	NL	NL	NL	NL
Steel lighting system support pole structures	15.6.10	1.5	1.5	1.5	NL	NL	NL	NL	NL
All other self-supporting structures, tanks, or vessels not covered above or by reference standards that are not similar to buildings		1.25	2	2.5	NL	NL	50	50	50

[a] NL = no limit; NP = not permitted.
[b] For the purpose of height limit determination, the height of the structure shall be taken as the height to the top of the structural frame making up the primary seismic force-resisting system.
[c] If a section is not indicated in the detailing requirements column, no specific detailing requirements apply.
[d] See Section 15.7.3.a for the application of the overstrength factors, Ω_0, for tanks and vessels.
[e] Detailed with an essentially complete vertical load-carrying frame.
[f] Sections 15.7.10.5(a) and 15.7.10.5(b) shall be applied for any risk category.
[g] The concrete columns shall have slenderness ratio $L/r \leq 22$.

The value of C_s shall not be taken as less than 0.03.

In addition, for nonbuilding structures located where $S_1 \geq 0.6g$, the minimum specified value in Equation (12.8-6) shall be replaced by

$$C_s = 0.8S_1/(R/I_e) \qquad (15.4\text{-}2)$$

EXCEPTION: Tanks and vessels that are designed to AWWA D100, AWWA D103, API 650 (Appendix E), and API 620 (Appendix L), as modified by this standard, and stacks and chimneys that are designed to ACI 307 as modified by this standard, shall be subject to the larger of the minimum base shear value defined by the reference document or the value determined by replacing Equation (12.8-5) with the following:

$$C_s = 0.044S_{DS}I_e \qquad (15.4\text{-}3)$$

The value of C_s shall not be taken as less than 0.01.

In addition, for nonbuilding structures located where $S_1 \geq 0.6g$, the minimum specified value in Equation (12.8-6) shall be replaced by

$$C_s = 0.5S_1/(R/I_e) \qquad (15.4\text{-}4)$$

Minimum base shear requirements need not apply to the convective (sloshing) component of liquid in tanks.

3. The Importance Factor, I_e, shall be as set forth in Section 15.4.1.1.
4. The vertical distribution of the lateral seismic forces in nonbuilding structures covered by this section shall be determined
   (a) Using the requirements of Section 12.8.3, or
   (b) Using the procedures of Section 12.9.1, or
   (c) In accordance with the reference document applicable to the specific nonbuilding structure.
5. Provided the mass locations for the structure, any contents, and any supported structural or nonstructural elements (including but not limited to piping and stairs) that could contribute to the mass or stiffness of the structure are accounted for and quantified in the analysis, the accidental torsion requirements of Section 12.8.4.2 need not be accounted for:
   (a) Rigid nonbuilding structures, or
   (b) Nonbuilding structures not similar to buildings and designed with R values less than or equal to 3.5, or
   (c) Nonbuilding structures similar to buildings and designed with R values less than or equal to 3.5, provided one of the following conditions is met:

@seismicisolation
@seismicisolation

(i) The calculated center of rigidity at each diaphragm is greater than 5% of the plan dimension of the diaphragm in each direction from the calculated center of mass of the diaphragm, or
(ii) The structure does not have a Type 1 horizontal torsional irregularity, and the structure has at least two lines of lateral resistance in each of two major axis directions. At least one line of lateral resistance shall be provided a distance of not less than 20% of the structure's plan dimension from the center of mass on each side of the center of mass.

In addition, structures designed to this section shall be analyzed using a 3D representation in accordance with Section 12.7.3.

6. For nonbuilding structural systems containing liquids, gases, and granular solids supported at the base as defined in Section 15.7.1, the minimum seismic design force shall not be less than that required by the reference document for the specific system.
7. Where a reference document provides a basis for the earthquake-resistant design of a particular type of nonbuilding structure covered by Chapter 15, such a standard shall not be used unless the following limitations are met:
   (a) The seismic ground accelerations and seismic coefficients shall be in conformance with the requirements of Section 11.4.
   (b) The values for total lateral force and total base overturning moment used in design shall not be less than 80% of the base shear value and overturning moment, each adjusted for the effects of soil–structure interaction that is obtained using this standard.
8. The base shear is permitted to be reduced in accordance with Section 19.2 to account for the effects of foundation damping from soil–structure interaction. In no case shall the reduced base shear be less than $0.7V$.
9. Unless otherwise noted in Chapter 15, the effects on the nonbuilding structure caused by gravity loads and seismic forces shall be combined in accordance with the factored load combinations as presented in Section 2.3.
10. Where specifically required by Chapter 15, the design seismic force on nonbuilding structures shall be as defined in Section 12.4.3.

15.4.1.1 Importance Factor The Importance Factor, I_e, and risk category for nonbuilding structures are based on the relative hazard of the contents and the function. The value of I_e shall be the largest value determined by the following:

(a) Applicable reference document listed in Chapter 23,
(b) The largest value as selected from Table 1.5-2, or
(c) As specified elsewhere in Chapter 15.

15.4.2 Rigid Nonbuilding Structures Nonbuilding structures that have a fundamental period, T, less than 0.06 s, including their anchorages, shall be designed for the lateral force obtained from the following:

$$V = 0.30 S_{DS} W I_e \tag{15.4-5}$$

where

V = Total design lateral seismic base shear force applied to a nonbuilding structure,
S_{DS} = Site design response acceleration as determined from Section 11.4.5,
W = Nonbuilding structure operating weight, and
I_e = Importance Factor determined in accordance with Section 15.4.1.1.

The force shall be distributed with height in accordance with Section 12.8.3.

15.4.3 Loads The seismic effective weight, W, for nonbuilding structures shall include the dead load and other loads as defined for structures in Section 12.7.2. For purposes of calculating design seismic forces in nonbuilding structures, W also shall include all normal operating contents for items such as tanks, vessels, bins, hoppers, and the contents of piping. W shall include snow and ice loads where these loads constitute 25% or more of W or where required by the Authority Having Jurisdiction based on local environmental characteristics.

15.4.4 Fundamental Period The fundamental period, T, of the nonbuilding structure shall be determined using the structural properties and deformation characteristics of the resisting elements in a properly substantiated analysis as indicated in Section 12.8.2. Alternatively, the fundamental period is permitted to be computed from the following equation:

$$T = 2\pi \sqrt{\frac{\sum_{i=1}^{n} w_i \delta_i^2}{g \sum_{i=1}^{n} f_i \delta_i}} \tag{15.4-6}$$

where the values of f_i represent any lateral force distribution in accordance with the principles of structural mechanics. The elastic deflections, δ_i, shall be calculated using the applied lateral forces, f_i. Equations (12.8-7), (12.8-8), (12.8-9), and (12.8-10) shall not be used for determining the period of a nonbuilding structure.

15.4.5 Drift Limit The drift limit of Section 12.12.1 need not apply to nonbuilding structures if a rational analysis indicates that the limit can be exceeded without adversely affecting structural stability or attached or interconnected components and elements such as walkways and piping.

15.4.6 P-Delta For nonbuilding structures similar to buildings, P-delta effects shall be evaluated using the requirements of Section 12.8.7. For nonbuilding structures not similar to buildings, the requirements of Section 12.8.7 do not apply. For nonbuilding structures not similar to buildings, P-delta effects on design forces and drifts induced by these effects shall be explicitly considered in the design of the structure. P-delta effects for nonbuilding structures not similar to buildings shall be based on displacements determined by an elastic analysis multiplied by C_d/I_e, using the appropriate C_d value from Table 15.4-2.

15.4.7 Drift, Deflection, and Structure Separation Drift, deflection, and structure separation calculated using strength-level seismic forces shall be determined in accordance with this standard unless specifically amended in Chapter 15.

15.4.8 Site-Specific Response Spectra Where required by a reference document or the Authority Having Jurisdiction, specific types of nonbuilding structures shall be designed for

@seismicisolation
@seismicisolation

site-specific criteria that account for local seismicity and geology, expected recurrence intervals, and magnitudes of events from known seismic hazards (see Section 11.4.8 of this standard). If a longer recurrence interval is defined in the reference document for the nonbuilding structure, such as liquefied natural gas (LNG) tanks (NFPA 59A), the recurrence interval required in the reference document shall be used.

15.4.9 Anchors in Concrete or Masonry

15.4.9.1 Anchors in Concrete Anchors in concrete used for nonbuilding structure anchorage shall be designed in accordance with Chapter 17 of ACI 318.

15.4.9.2 Anchors in Masonry Anchors in masonry used for nonbuilding structure anchorage shall be designed in accordance with TMS 402. Anchors shall be designed to be governed by the tensile or shear strength of a ductile steel element.

EXCEPTION: Anchors shall be permitted to be designed so that either

(a) The attachment that the anchor is connecting to the structure undergoes ductile yielding at a load level corresponding to anchor forces not greater than the design strength of the anchor, or
(b) The anchors resist the load combinations in accordance with Section 12.4.3, including Ω_0 as given in Tables 15.4-1 and 15.4-2.

15.4.9.3 Post-Installed Anchors in Concrete and Masonry Post-installed anchors in concrete shall be prequalified for seismic applications in accordance with ACI 355.2 or other approved qualification procedures. Post-installed anchors in masonry shall be prequalified for seismic applications in accordance with approved qualification procedures.

15.4.9.4 ASTM F1554 Anchors When ASTM F1554 Grade 36 anchors are specified and are designed as ductile anchors in accordance with ACI 318, Section 17.10.5.3(a), or where the design must meet the requirements of Section 15.7.5 or 15.7.11.7(b) of this standard, substitution of weldable ASTM F1554 Grade 55 (with Supplementary Requirement S1) anchors shall be prohibited.

15.4.10 Requirements for Nonbuilding Structure Foundations on Liquefiable Sites Nonbuilding structure foundations on liquefiable sites shall comply with Section 12.13.9 and the requirements of Section 15.4.10.1.

15.4.10.1 Nonbuilding Structures on Shallow Foundations Nonbuilding structures shall not be permitted to be supported on shallow foundations at liquefiable sites unless it can be demonstrated that the structure's foundation, superstructure, and connecting systems can be designed to accommodate the soil strength loss, lateral spreading, and total and differential settlements induced by MCE_G earthquake ground motions indicated in the geotechnical investigation report.

15.4.11 Material Requirements The requirements regarding specific materials in Chapter 14 shall be applicable unless specifically exempted in Chapter 15.

15.5 NONBUILDING STRUCTURES SIMILAR TO BUILDINGS

15.5.1 General Nonbuilding structures similar to buildings as defined in Section 11.2 shall be designed in accordance with this standard as modified by this section and the specific reference documents. This general category of nonbuilding structures shall be designed in accordance with the seismic requirements of this standard and the applicable portions of Section 15.4. The combination of load effects, E, shall be determined in accordance with Section 12.4.

15.5.2 Pipe Racks

15.5.2.1 Design Basis In addition to the requirements of Section 15.5.1, pipe racks supported at the base of the structure shall be designed to meet the force requirements of Section 12.8 or 12.9.1. Displacements of the pipe rack and potential for interaction effects (pounding of the piping system) shall be considered using the amplified deflections calculated as

$$\delta_x = \frac{C_d \delta_{xe}}{I_e} \tag{15.5-1}$$

where

C_d = Deflection amplification factor in Table 15.4-1,
δ_{xe} = Deflections determined using the prescribed seismic design forces of this standard, and
I_e = Importance Factor determined in accordance with Section 15.4.1.1.

See Section 13.6.2 for the design of piping systems and their attachments. Friction resulting from gravity loads shall not be considered to provide resistance to seismic forces.

15.5.3 Storage Racks Storage racks constructed from steel and supported at or below grade shall be designed in accordance with Section 15.5.3.1 or 15.5.3.2, as applicable, and the requirements in Section 15.5.3.3.

15.5.3.1 Steel Storage Racks Steel storage racks supported at or below grade shall be designed in accordance with ANSI/RMI MH 16.1, its force and displacement requirements, and the seismic design ground motion values determined according to Section 11.4, except as follows:

15.5.3.1.1 Modify Section 7.1.2 of ANSI/RMI MH 16.1 as follows:

7.1.2 Base Plate Design

Once the required bearing area has been determined from the allowable bearing stress, F'_p, the minimum thickness of the base plate is determined by rational analysis or by appropriate test using a test load 1.5 times the ASD design load or the factored LRFD load. Design forces that include seismic loads for anchorage of steel storage racks to concrete or masonry shall be determined using load combinations with overstrength provided in Section 12.4.3.1 of ASCE/SEI 7. The overstrength factor shall be taken as 2.0.

Anchorage of steel storage racks to concrete shall be in accordance with the requirements of Section 15.4.9 of ASCE/SEI 7. Upon request, information shall be given to the owner or the owner's agent on the location, size, and pressures under the column base plates of each type of upright frame in the installation. When rational analysis is used to determine base plate thickness, and other applicable standards do not apply, the base plate shall be permitted to be designed for the following loading conditions, where applicable: [balance of section unchanged]

15.5.3.1.2 Modify Section 7.1.4 of ANSI/RMI MH 16.1 as follows:

7.1.4 Shims

Shims may be used under the base plate to maintain the plumbness and/or levelness of the storage rack. The shims shall

@seismicisolation

be made of a material that meets or exceeds the design bearing strength (LRFD) or allowable bearing strength (ASD) of the floor. The shim size and location under the base plate shall be equal to or greater than the required base plate size and location.

~~In no case shall the total thickness of a shim stack under a base plate exceed six times the diameter of the largest anchor bolt used in that base.~~

Shims stacks ~~having a total thickness greater than two and less than or equal to six times the anchor bolt diameter under bases with only one anchor bolt~~ shall be interlocked or welded together in a fashion that is capable of transferring all the shear forces at the base.

~~Shims stacks having a total thickness of less than or equal to two times the anchor bolt diameter need not be interlocked or welded together.~~

Bending in the anchor associated with shims or grout under the base plate shall be taken into account in the design of anchor bolts.

15.5.3.2 Steel Cantilevered Storage Racks Steel cantilevered storage racks supported at or below grade shall be designed in accordance with ANSI/RMI MH 16.3, its force and displacement requirements, and the seismic design ground motion values determined according to Section 11.4, except as follows.

15.5.3.2.1 Modify Section 8.5.1 of ANSI/RMI MH 16.3 as follows:

8.5.1 Anchor Bolt Design

Anchorage of steel cantilevered storage racks to concrete shall be in accordance with the requirements of Section 15.4.9 of ASCE/SEI 7. The redundancy factor in the load combinations in Section 2.1 and 2.2 shall be 1.0. Design forces that include seismic loads for anchorage of steel cantilevered storage racks to concrete or masonry shall be determined using load combinations with overstrength provided in Sections 2.3.6 or 2.4.5 of ASCE/SEI 7.

If shims are used under the base plate to maintain the plumbness and/or levelness of the steel cantilevered storage rack, the shims stacks shall be interlocked or welded together in a fashion that is capable of transferring all the shear forces at the base. Bending in the anchor associated with shims or grout under the base plate shall be taken into account in the design of anchor bolts.

15.5.3.3 Alternative As an alternative to ANSI/RMI MH 16.1 or 16.3, as modified, storage racks shall be permitted to be designed in accordance with the requirements of Sections 15.1, 15.2, 15.3, 15.5.1, and 15.5.3.3.1 through 15.5.3.3.4 of this standard.

15.5.3.3.1 General Requirements Storage racks shall satisfy the force requirements of this section. The Importance Factor, I_e, for storage racks in structures open to the public, such as warehouse retail stores, shall be taken equal to 1.5.

EXCEPTION: Steel storage racks supported at the base are permitted to be designed as structures with an R of 4, provided the seismic requirements of this standard are met. Higher values of R are permitted to be used where the detailing requirements of reference documents listed in Section 14.1.1 are met. The Importance Factor, I_e, for steel storage racks in structures open to the public, such as warehouse retail stores, shall be taken as equal to 1.5.

15.5.3.3.2 Operating Weight Storage racks shall be designed for each of the following conditions of operating weight, W or W_p:

(a) Weight of the rack plus every storage level loaded to 67% of its rated load capacity; and
(b) Weight of the rack plus the highest storage level only, loaded to 100% of its rated load capacity.

The design shall consider the actual height of the center of mass of each storage load component.

15.5.3.3.3 Vertical Distribution of Seismic Forces For all storage racks, the vertical distribution of seismic forces shall be as specified in Section 12.8.3 and in accordance with the following:

(a) The base shear, V, of the typical structure shall be the base shear of the steel storage rack where loaded in accordance with Section 15.5.3.2.
(b) The base of the structure shall be the floor supporting the steel storage rack. Each steel storage level of the rack shall be treated as a level of the structure with heights h_i and h_x measured from the base of the structure.
(c) The factor k is permitted to be taken as 1.0.

15.5.3.3.4 Seismic Displacements Storage rack installations shall accommodate the seismic displacement of the steel storage racks and their contents relative to all adjacent or attached components and elements. The assumed total relative displacement for steel storage racks shall be not less than 5% of the structural height above the base, h_n, unless a smaller value is justified by test data or analysis in accordance with Section 11.1.4.

15.5.4 Electrical Power-Generating Facilities

15.5.4.1 General Electrical power-generating facilities are power plants that generate electricity by steam turbines, combustion turbines, diesel generators, or similar turbomachinery.

15.5.4.2 Design Basis In addition to the requirements of Section 15.5.1, electrical power-generating facilities shall be designed using this standard and the appropriate factors contained in Section 15.4.

15.5.5 Structural Towers for Tanks and Vessels

15.5.5.1 General In addition to the requirements of Section 15.5.1, structural towers that support tanks and vessels and are not integral with the tank shall be designed to meet the requirements of Section 15.3. In addition, the following special considerations shall be included:

(a) The distribution of the lateral base shear from the tank or vessel onto the supporting structure shall consider the relative stiffness of the tank and resisting structural elements.
(b) The distribution of the vertical reactions from the tank or vessel onto the supporting structure shall consider the relative stiffness of the tank and resisting structural elements. Where the tank or vessel is supported on grillage beams, the calculated vertical reaction caused by weight and overturning shall be increased at least 20% to account for nonuniform support. The grillage beam and vessel attachment shall be designed for this increased design value.
(c) Seismic displacements of the tank and vessel shall consider the deformation of the support structure where determining P-delta effects or evaluating required clearances to prevent pounding of the tank on the structure. P-delta effects shall be based on displacements determined by an elastic analysis multiplied by C_d/I_e using the appropriate C_d value from Table 15.4-2.

Tanks and vessels supported by structural towers that are integral to the tank or vessel shall be designed according to Section 15.7.10.1.

15.5.6 Piers and Wharves

15.5.6.1 General Piers and wharves are structures located in waterfront areas that project into a body of water or that parallel the shoreline.

@seismicisolation
@seismicisolation

15.5.6.2 Design Basis In addition to the requirements of Section 15.5.1, piers and wharves that are accessible to the general public, such as cruise ship terminals and piers with retail or commercial offices or restaurants, shall be designed to comply with this standard. Piers and wharves that are not accessible to the general public are beyond the scope of this section.

The design shall account for the effects of liquefaction and soil failure collapse mechanisms and shall consider all applicable marine loading combinations, such as mooring, berthing, wave, and current on piers and wharves, as required. Structural detailing shall consider the effects of the marine environment.

15.6 GENERAL REQUIREMENTS FOR NONBUILDING STRUCTURES NOT SIMILAR TO BUILDINGS

Nonbuilding structures that do not have lateral and vertical seismic force-resisting systems that are similar to buildings shall be designed in accordance with this standard as modified by this section and the specific reference documents. Loads and load distributions shall not be less demanding than those determined in this standard. The combination of earthquake load effects, E, shall be determined in accordance with Section 12.4.2.

EXCEPTION: The redundancy factor, ρ, per Section 12.3.4 shall be taken as 1.

15.6.1 Earth-Retaining Structures This section applies to all earth-retaining structures assigned to Seismic Design Category D, E, or F. The lateral earth pressures caused by earthquake ground motions shall be determined in accordance with Section 11.8.3. The risk category shall be determined by the proximity of the earth-retaining structure to other buildings and structures. If failure of the earth-retaining structure would affect the adjacent building or structure, the risk category shall not be less than that of the adjacent building or structure.

Earth-retaining walls are permitted to be designed for seismic loads as either yielding or nonyielding walls. Cantilevered reinforced concrete or masonry retaining walls shall be assumed to be yielding walls and shall be designed as simple flexural wall elements.

15.6.2 Trussed Towers, Chimneys, and Stacks

15.6.2.1 General Trussed towers shall be designed to resist seismic lateral forces determined in accordance with Section 15.4. A system that meets the definition of braced frame and conforms to Section 15.5, "Nonbuilding Structures Similar to Buildings," and Table 15.4-1 shall not be considered a trussed tower in Table 15.4-2.

Chimneys and stacks are permitted to be either lined or unlined and shall be constructed from concrete, steel, or masonry. Steel stacks, concrete stacks, steel chimneys, concrete chimneys, and liners shall be designed to resist seismic lateral forces determined from a substantiated analysis using reference documents. Interaction of the stack or chimney with the liners shall be considered. A minimum separation shall be provided between the liner and chimney equal to C_d times the calculated differential lateral drift.

15.6.2.2 Concrete Chimneys and Stacks Concrete chimneys and stacks shall be designed in accordance with the requirements of ACI 307, except that (1) the design base shear shall be determined based on Section 15.4.1 of this standard, (2) the seismic coefficients shall be based on the values provided in Table 15.4-2, and (3) openings shall be detailed as described in the next paragraph. When modal response spectrum analysis is used for design, the procedures of Section 12.9 shall be permitted to be used.

For concrete chimneys and stacks assigned to Seismic Design Categories D, E, and F, splices for vertical rebar shall be staggered such that no more than 50% of the bars are spliced at any section and alternate lap splices are staggered by the development length. In addition, where the loss of cross-sectional area is greater than 10%, cross sections in the regions of breachings/openings shall be designed and detailed for vertical force, shear force, and bending moment demands along the vertical direction, determined for the affected cross section using an overstrength factor of 1.5. The region where the overstrength factor applies shall extend above and below the opening(s) by a distance equal to half of the width of the largest opening in the affected region. Appropriate reinforcement development lengths shall be provided beyond the required region of overstrength. The jamb regions around each opening shall be detailed using the column tie requirements in Section 10.7.6 of ACI 318. Such detailing shall extend for a jamb width of a minimum of two times the wall thickness and for a height of the opening height plus twice the wall thickness above and below the opening but no less than the development length of the longitudinal bars. Where the existence of a footing or base mat precludes the ability to achieve the extension distance below the opening and within the stack, the jamb reinforcing shall be extended and developed into the footing or base mat. The percentage of longitudinal reinforcement in jamb regions shall meet the requirements of Section 10.6.1.1 of ACI 318 for compression members.

15.6.2.3 Steel Chimneys and Stacks Steel chimneys and stacks shall be designed in accordance with the requirements of ASME STS-1, except that (1) the design base shear shall be determined based on Section 15.4.1 of this standard, (2) the seismic coefficients shall be based on the values provided in Table 15.4-2, and (3) ASME STS-1, Section 4.3.5, and Nonmandatory Appendix D Table D-1, Table D-2, Figure D-2, and Figure D-2a shall not be used. When modal response spectrum analysis is used for design, the procedures of Section 12.9 shall be permitted to be used.

15.6.3 Amusement Structures Amusement structures are permanently fixed structures constructed primarily for the conveyance and entertainment of people. Amusement structures shall be designed to resist seismic lateral forces determined in accordance with Section 15.4.

15.6.4 Special Hydraulic Structures Special hydraulic structures are structures that are contained inside liquid-containing structures. These structures are exposed to liquids on both wall surfaces at the same head elevation under normal operating conditions. Special hydraulic structures are subjected to out-of-plane forces only during an earthquake, when the structure is subjected to differential hydrodynamic fluid forces. Examples of special hydraulic structures include separation walls, baffle walls, weirs, and other similar structures.

15.6.4.1 Design Basis Special hydraulic structures shall be designed for out-of-phase movement of the fluid. Unbalanced forces from the motion of the liquid must be applied simultaneously "in front of" and "behind" these elements.

Structures subject to hydrodynamic pressures induced by earthquakes shall be designed for rigid-body and sloshing-liquid forces and their own inertia force. The height of sloshing shall be determined and compared with the freeboard height of the structure. Interior elements, such as baffles or roof supports, also shall be designed for the effects of unbalanced forces and sloshing.

15.6.5 Secondary Containment Systems Secondary containment systems, such as impoundment dikes and walls, shall meet the requirements of the applicable standards for tanks and vessels and of the Authority Having Jurisdiction.

@seismicisolation

Secondary containment systems shall be designed to withstand the effects of the maximum considered earthquake ground motion where empty and two-thirds of the maximum considered earthquake ground motion where full, including all hydrodynamic forces, as determined in accordance with the procedures of Section 11.4. Where it is determined by the risk assessment required by Section 1.5.3 or by the Authority Having Jurisdiction that the site may be subject to aftershocks of the same magnitude as the maximum considered motion, secondary containment systems shall be designed to withstand the effects of the maximum considered earthquake ground motion where full, including all hydrodynamic forces, as determined in accordance with the procedures of Section 11.4.

15.6.5.1 Freeboard Sloshing of the liquid within the secondary containment area shall be considered in determining the height of the impoundment. Where the primary containment has not been designed with a reduction in the structure category (i.e., no reduction in Importance Factor, I_e) as permitted by Section 1.5.3, no freeboard provision is required. Where the primary containment has been designed for a reduced structure category (i.e., Importance Factor I_e reduced) as permitted by Section 1.5.3, a minimum freeboard, δ_s, shall be provided where

$$\delta_s = 0.42DS_{ac} \tag{15.6-1}$$

where S_{ac} is the spectral acceleration of the convective component and is determined according to the procedures of Section 15.7.6.1 using 0.5% damping. For circular impoundment dikes, D shall be taken as the diameter of the impoundment dike. For rectangular impoundment dikes, D shall be taken as the plan dimension of the impoundment dike, L, for the direction under consideration.

15.6.6 Telecommunication Towers Self-supporting and guyed telecommunication towers shall be designed to resist seismic lateral forces determined in accordance with ANSI/TIA-222-H. The seismic design ground motion values shall be determined according to Section 11.4.

15.6.7 Steel Tubular Support Structures for Onshore Wind Turbine Generator Systems Steel tubular support structures for onshore wind turbine generator systems shall be designed to resist seismic lateral forces determined in accordance with Section 15.4.

15.6.8 Ground-Supported Cantilever Walls or Fences

15.6.8.1 General Ground-supported cantilever walls or fences 6 ft (1.83 m) or greater in height shall satisfy the requirements of this section. Earth-retaining structures shall comply with Section 15.6.1.

15.6.8.2 Design Basis Walls or fences shall be designed to resist earthquake ground motions in accordance with Section 15.4. Detailed plain and ordinary plain concrete or masonry walls or fences and ordinary plain autoclaved aerated concrete (AAC) walls or fences are not permitted in Seismic Design Category C, D, E, and F.

15.6.9 Reinforced Concrete Tabletop Structure for Rotating Equipment and Process Vessels or Drums Slab-column reinforced concrete moment frames designed per Section 15.4 qualify for the seismic design parameters for the tabletop structure entries in Table 15.4-2 if the following requirements are satisfied:

(a) The flexural capacity of each column under all load combinations is less than two-thirds the flexural capacity of the slab and less than two-thirds the flexural capacity of the foundation that supports the column,
(b) The thickness of the slab is not less than 3 ft (0.91 m), and
(c) The design of the reinforced concrete members satisfies ACI 318, with the exception of Chapter 18.

***15.6.9.1 Tabletop Structures Designed with* R = 2.0** Tabletop structures designed with $R = 2.0$ shall be supported by at least six columns, satisfy the requirements listed in Section 15.6.9, and be detailed to satisfy Section 18.3.3 of ACI 318.

***15.6.9.2 Tabletop Structures Designed with* R = 2.5** Tabletop structures designed with $R = 2.5$ shall be detailed to satisfy the requirements of ACI 318 for ordinary moment frames. Items (a), (b), and (c) in Section 15.6.9 need not be satisfied. Section 18.3.4 of ACI 318 shall be deemed to be satisfied if the total area of vertical reinforcement in the column does not exceed 2% of the gross concrete cross section of the column. If there is more reinforcement in the column and if the flexural capacity of the column is greater than the flexural capacity of the slab or beam, the joint shear force, V_u, shall be computed with forces in the slab reinforcement that are in equilibrium with the seismic load assuming the vertical bars on the tension face of the column have reached yield.

***15.6.9.3 Tabletop Structures Designed with* R = 4.0** Tabletop structures designed with $R = 4.0$ shall be detailed to satisfy the requirements of ACI 318 for intermediate moment frames. Items (a), (b), and (c) of 15.6.9 need not be satisfied.

15.6.10 Steel Lighting System Support Pole Structures Steel lighting system support pole structures shall be designed in accordance with the seismic requirements of ASCE 72, except that the seismic design ground motion values shall be determined according to Section 11.4.

15.7 TANKS AND VESSELS

15.7.1 General This section applies to all tanks, vessels, bins, silos, and similar containers storing liquids, gases, and granular solids supported at the base (hereafter referred to generically as "tanks and vessels"). Tanks and vessels covered herein include reinforced concrete, prestressed concrete, steel, aluminum, and fiber-reinforced plastic materials. Tanks supported on elevated levels in buildings shall be designed in accordance with Section 15.3.

15.7.2 Design Basis Tanks and vessels storing liquids, gases, and granular solids shall be designed in accordance with this standard and shall be designed to meet the requirements of the applicable reference documents listed in Chapter 23. Resistance to seismic forces shall be determined from a substantiated analysis based on the applicable reference documents listed in Chapter 23.

(a) Damping for the convective (sloshing) force component shall be taken as 0.5%.
(b) Impulsive and convective components shall be combined by the direct sum or the square root of the sum of the squares (SRSS) method where the modal periods are separated. If significant modal coupling may occur, the complete quadratic combination (CQC) method shall be used.

@seismicisolation

(c) Vertical earthquake forces shall be considered in accordance with the applicable reference document. If the reference document permits the user the option of including or excluding the vertical earthquake force to comply with this standard, it shall be included. For tanks and vessels not covered by a reference document, the forces caused by the vertical acceleration shall be defined as follows:

(i) *Hydrodynamic vertical and lateral forces in non-cylindrical tank walls*. The increase in hydrostatic pressures caused by the vertical excitation of the contained liquid shall correspond to an effective increase in unit weight, γ_L, of the stored liquid equal to $0.4S_{av}\gamma_L$, where S_{av} is taken as the peak of the vertical response spectrum defined in Section 11.9.

(ii) *Hydrodynamic hoop forces in cylindrical tank walls*. In a cylindrical tank wall, the hoop force per unit height, N_h, at height y from the base, associated with the vertical excitation of the contained liquid, shall be calculated as follows:

$$N_h = \frac{S_{av}}{R}\gamma_L(H_L - y)\left(\frac{D_i}{2}\right) \qquad (15.7\text{-}1)$$

where

D_i = Inside tank diameter,
H_L = Liquid height inside the tank,
y = Distance from base of the tank to height being investigated,
γ_L = Unit weight of stored liquid, and
S_{av} = Vertical seismic parameter from Section 11.9, determined natural period of vibration of vertical liquid motion.

The hoop force associated with the vertical excitation of the liquid shall be combined with the impulsive and convective components by the direct sum or SRSS method.

(iii) *Vertical inertia forces in cylindrical and rectangular tank walls*. Vertical inertia forces associated with the vertical acceleration of the structure itself shall be taken as equal to $0.4S_{av}W$, where S_{av} is taken as the peak of the vertical response spectrum defined in Section 11.9.

15.7.3 Strength and Ductility Structural members that are part of the seismic force-resisting system shall be designed to provide the following.

(a) Connections to seismic force-resisting elements, excluding anchors (bolts or rods) embedded in concrete, shall be designed to develop forces calculated using the seismic load effects including overstrength of Section 12.4.3. For anchors (bolts or rods) embedded in concrete, the design of the anchor embedment shall meet the requirements of Section 15.7.5. In addition, the connection of the anchors to the tank or vessel shall be designed to develop the lesser of the strength of the anchor in tension as determined by API 650 or AWWA D100 or forces calculated using the seismic load effects including overstrength of Section 12.4.3. The overstrength requirements of Section 12.4.3 and the Ω_0 values tabulated in Table 15.4-2 do not apply to the design of walls, including interior walls, of tanks or vessels.

(b) Penetrations, manholes, and openings in shell elements shall be designed to maintain the strength and stability of the shell to carry tensile and compressive membrane shell forces.

(c) Support towers for tanks and vessels, where the support tower is integral with the tank or vessel, with irregular bracing, unbraced panels, asymmetric bracing, or concentrated masses shall be designed using the requirements of Section 12.3.2 for irregular structures. Support towers using chevron or eccentrically braced framing shall comply with the seismic requirements of this standard. Support towers using tension-only bracing shall be designed such that the full cross section of the tension element can yield during overload conditions.

(d) In support towers for tanks and vessels, where the support tower is integral with the tank or vessel, compression struts that resist the reaction forces from tension braces shall be designed to resist the lesser of the yield load of the brace, A_gF_y, or forces calculated using the seismic load effects including overstrength of Section 12.4.3.

(e) The vessel stiffness relative to the support system (foundation, support tower, skirt, etc.) shall be considered in determining forces in the vessel, the resisting elements, and the connections.

(f) For concrete liquid-containing structures, system ductility and energy dissipation under allowable stress design level loads shall not be allowed to be achieved by inelastic deformations to such a degree as to jeopardize the serviceability of the structure. Stiffness degradation and energy dissipation shall be allowed to be obtained either through limited microcracking, or by means of lateral force resistance mechanisms that dissipate energy without damaging the structure.

15.7.4 Flexibility of Piping Attachments Design of piping systems connected to tanks and vessels shall consider the potential movement of the connection points during earthquakes and provide sufficient flexibility to avoid release of the product by failure of the piping system. The piping system and supports shall be designed so as not to impart significant mechanical loading on the attachment to the tank or vessel shell. Mechanical devices that add flexibility, such as bellows, expansion joints, and other flexible apparatus, are permitted to be used where they are designed for seismic displacements and defined operating pressure.

Unless otherwise calculated, the minimum displacements in Table 15.7-1 shall be assumed. For attachment points located above the support or foundation elevation, the displacements in Table 15.7-1 shall be increased to account for drift of the tank or vessel relative to the base of support. The piping system and tank connection shall also be designed to tolerate C_d times the displacements given in Table 15.7-1 without rupture, although permanent deformations and inelastic behavior in the piping supports and tank shell are permitted. For attachment points located above the support or foundation elevation, the displacements in Table 15.7-1 shall be increased to account for drift of the tank or vessel. The values given in Table 15.7-1 do not include the influence of relative movements of the foundation and piping anchorage points caused by foundation movements (e.g., settlement or seismic displacements). The effects of the foundation movements shall be included in the piping system design, including the determination of the mechanical loading on the tank or vessel, and the total displacement capacity of the mechanical devices intended to add flexibility.

@seismicisolation

Table 15.7-1. Minimum Design Displacements for Piping Attachments.

Condition	Minimum Design Displacement, in. (mm)
Mechanically Anchored Tanks and Vessels	
Upward vertical displacement relative to support or foundation	1 (25.4)
Downward vertical displacement relative to support or foundation	0.5 (12.7)
Range of horizontal displacement (radial and tangential) relative to support or foundation	0.5 (12.7)
Self-Anchored Tanks or Vessels (at Grade)	
Upward vertical displacement relative to support or foundation:	
If designed in accordance with a reference document as modified by this standard:	
Anchorage ratio less than or equal to 0.785 (indicates no uplift)	1 (25.4)
Anchorage ratio greater than 0.785 (indicates uplift)	4 (101.1)
If designed for seismic loads in accordance with this standard but not covered by a reference document:	
For tanks and vessels with diameter less than 40 ft (12.2 m)	8 (202.2)
For tanks and vessels with diameter equal to or greater than 40 ft (12.2 m)	12 (0.305)
Downward vertical displacement relative to support or foundation:	
For tanks with a ringwall/mat foundation	0.5 (12.7)
For tanks with a berm foundation	1 (25.4)
Range of horizontal displacement (radial and tangential) relative to support or foundation	2 (50.8)

Table 15.7-2. Anchorage Ratio.

Anchorage Ratio, J	Criteria
$J < 0.785$	No uplift under the design seismic overturning moment. The tank is self-anchored.
$0.785 < J < 1.54$	Tank is uplifting, but the tank is stable for the design load, provided that the shell compression requirements are satisfied. The tank is self-anchored.
$J > 1.54$	Tank is not stable and shall be mechanically anchored for the design load.

The anchorage ratio, J, for self-anchored tanks shall comply with the criteria shown in Table 15.7-2 and is defined as

$$J = \frac{M_{rw}}{D^2(w_t + w_a)} \tag{15.7-2}$$

where

$$w_t = \frac{W_s}{\pi D} + w_r \tag{15.7-3}$$

w_r = Roof load acting on the shell [lb/ft (N/m)] of shell circumference. Only permanent roof loads shall be included. Roof live load shall not be included;
w_a = Maximum weight of the tank contents that may be used to resist the shell overturning moment [lb/ft (N/m)] of shell circumference (w_a usually consists of an annulus of liquid limited by the bending strength of the tank bottom or annular plate);
M_{rw} = Overturning moment applied at the bottom of the shell caused by the seismic design loads [ft-lb (N-m)] (also known as the ringwall moment);
D = Tank diameter, ft (m), [ft (m)]; and
W_s = Total weight of tank shell [lb (N)].

15.7.5 Anchorage Tanks and vessels at grade are permitted to be designed without anchorage where they meet the requirements for self-anchored tanks in reference documents. Tanks and vessels supported above grade on structural towers or building structures shall be anchored to the supporting structure.

For the anchorage of steel tanks and vessels with a diameter or width greater than 5 ft (1.5 m) or a height greater than 10 ft (3.0 m) in Seismic Design Category B, anchorage shall be designed in accordance with Section 15.4.9.

For the anchorage of steel tanks and vessels with a diameter or width greater than 5 ft (1.5 m) or a height greater than 10 ft (3.0 m) in Seismic Design Categories C, D, E, and F, all of the following special detailing requirements shall apply:

(a) Anchorage shall be in accordance with Section 15.4.9.1, whereby the anchor embedment into the concrete shall be designed to develop the steel strength of the anchor in tension in accordance with ACI 318 Section, 17.10.5.3 (a), as given by ACI 318, Equation (17.6.1.2), or shall be designed using anchor reinforcement in accordance with ACI 318, Section 17.4.2.9, to develop the steel strength of the anchor in tension per ACI 318, Equation (17.6.1.2).
(b) The minimum gauge length of anchor rod, which is the length over which its elongation can occur, shall be at least eight times the rod diameter.
(c) Post-installed anchors are permitted to be used in accordance with Section 15.4.9.3, provided the anchor embedment into the concrete is sufficient to develop the steel strength of the anchor rod in tension.
(d) Where the special detailing requirements of this section apply, the load combinations of Section 12.4.3 that include overstrength do not apply.

For steel tanks and vessels with a diameter or width less than or equal to 5 ft (1.5 m) and a height less than or equal space to 10 ft (3.0 m) in Seismic Design Categories C, D, E, and F, anchorage shall be in accordance with Section 15.4.9.

15.7.6 Ground-Supported Storage Tanks for Liquids

15.7.6.1 General Ground-supported, flat-bottom tanks storing liquids shall be designed to resist the seismic forces as follows:

(a) For tanks or vessels storing liquids with a diameter or width less than or equal to 5 ft (1.5 m), the base shear and overturning moment shall be calculated as if the tank and

@seismicisolation

the entire contents act as an impulsive mass, using Equation (15.7-5). The convective mass shall be set equal to zero in Equation (15.7-6). The lateral force distribution shall be per API 650, API 620, AWWA D100, AWWA D110, AWWA D115, or ACI 350.3. The requirements of Section 15.7, including Section 15.7.6.2, shall apply.

(b) Tanks or vessels storing liquids with a diameter or width greater than 5 ft (1.5 m) shall be designed to consider the hydrodynamic pressures of the liquid in determining the equivalent lateral forces and lateral force distribution per the applicable reference documents listed in Chapter 23. The requirements of Section 15.7 including 15.7.6.2 shall apply.

15.7.6.2 Design Basis The design of tanks storing liquids shall consider the impulsive and convective (sloshing) effects and their consequences on the tank, foundation, and attached elements. The impulsive component corresponds to the high-frequency amplified response to the lateral ground motion of the tank roof, the shell, and the portion of the contents that moves in unison with the shell. The convective component corresponds to the low-frequency amplified response of the contents in the fundamental sloshing mode. Damping for the convective component shall be 0.5% for the sloshing liquid unless otherwise defined by the reference document. The following definitions shall apply:

D_i = Inside diameter of tank or vessel;
H_L = Design liquid height inside the tank or vessel;
L = Inside length of a rectangular tank, parallel to the direction of the earthquake force being investigated;
N_h = Hydrodynamic hoop force per unit height in the wall of a cylindrical tank or vessel;
T_c = Natural period of the first (convective) mode of sloshing;
T_i = Fundamental period of the tank structure and impulsive component of the content;
V_i = Base shear caused by impulsive component from weight of tank and contents;
V_c = Base shear caused by the convective component of the effective sloshing mass;
y = Distance from base of the tank to level being investigated; and
γ_L = Unit weight of stored liquid.

The seismic base shear is the combination of the impulsive and convective components:

$$V = V_i + V_c \tag{15.7-4}$$

where

$$V_i = \frac{S_{ai} W_i}{\left(\frac{R}{I_e}\right)} \tag{15.7-5}$$

and

$$V_c = \frac{S_{ac} I_e}{1.5} W_c \tag{15.7-6}$$

where

W_i = Impulsive weight (impulsive component of liquid, roof and equipment, shell, bottom, and internal elements);
W_c = Portion of the liquid weight sloshing; and
S_{ai} = Spectral acceleration as a multiplier of gravity, including the site impulsive components at period T_i and 5% damping. For $T_i \le T_s$,

$$S_{ai} = S_{DS} \tag{15.7-7}$$

For $T_s < T_i \le T_L$,

$$S_{ai} = \frac{S_{D1}}{T_i} \tag{15.7-8}$$

For $T_i > T_L$,

$$S_{ai} = \frac{S_{D1} T_L}{T_i^2} \tag{15.7-9}$$

NOTES:

1. Where a reference document is used in which the spectral acceleration for the tank shell and the impulsive component of the liquid are independent of T_i, then $S_{ai} = S_{DS}$.
2. S_{ai} determined from Equations (15.7-8) and (15.7-9) shall not be less than the minimum values required in Section 15.4.1, Item 2, multiplied by R/I_e.
3. Impulsive and convective seismic forces for tanks are permitted to be combined using the SRSS method in lieu of the direct sum method shown in Section 15.7.6 and its related subsections.

S_{ac} = Spectral acceleration of the sloshing liquid (convective component), based on the sloshing period T_c and 0.5% damping.

For $T_c \le T_L$,

$$S_{ac} = \frac{1.5 S_{D1}}{T_c} \le S_{DS} \tag{15.7-10}$$

For $T_c > T_L$,

$$S_{ac} = \frac{1.5 S_{D1} T_L}{T_c^2} \tag{15.7-11}$$

EXCEPTIONS:

1. Where the design spectral acceleration parameter, S_a, determined in accordance with either Section 11.4.5.1 or Chapter 21 is available, the value of S_{ai} determined by Equation (15.7-7), (15.7-8), or (15.7-9) is permitted to be taken as the value of S_a at the period T_i. Where the period T_i is less than the period at which S_a is maximum, the maximum value of S_a shall be used. The value of S_{ai} shall not be less than the minimum values required in Section 15.4.1, Item 2, multiplied by R/I_e. When Exception 1 is invoked, the value of S_{ac} must be determined using Exception 2.
2. Where the design spectral acceleration parameter, S_a, determined in accordance with either Section 11.4.5.1 or Chapter 21 is available, the value of S_{ac} determined by Equation (15.7-10) or (15.7-11) is permitted to be taken as 1.5 times the value of S_a at the period T_c. The value of 1.5 S_{ac} need not exceed the maximum value of S_a. When Exception 2 is invoked, the value of S_{ai} must be determined using Exception 1.
3. For $T_c > 4\,s$, S_{ac} is permitted to be determined by a site-specific study using one or more of the following methods: (a) the procedures in Chapter 21, provided such procedures, which rely on ground-motion attenuation equations for computing response spectra, cover the natural period band containing T_c; (b) ground-motion simulation methods that use seismological models of fault rupture and wave

@seismicisolation

propagation; and (c) analysis of representative strong-motion accelerogram data with reliable long-period content extending to periods greater than T_c. Site-specific values of S_{ac} shall be based on one-standard-deviation determinations. However, in no case shall the value of S_{ac} be taken as less than the value determined in accordance with Equation (15.7-11) using 50% of the mapped value of T_L from Chapter 22.

The 80% limit on S_a required by Sections 21.3 and 21.4 shall not apply to the determination of site-specific values of S_{ac}, which satisfy the requirements of this exception. In determining the value of S_{ac}, the value of T_L shall not be less than 4 s, where

$$T_c = 2\pi\sqrt{\frac{D}{3.68\ g\tanh\left(\frac{3.68\ H}{D}\right)}} \tag{15.7-12}$$

where

D = Tank diameter, ft (m), [ft (m)],
H = Liquid height, ft (m), [ft (m)], and
g = Acceleration caused by gravity in consistent units.

15.7.6.2.1 Distribution of Hydrodynamic and Inertial Forces Unless otherwise required by the appropriate reference document listed in Chapter 23, the method given in ACI 350.3 is permitted to be used to determine the vertical and horizontal distribution of the hydrodynamic and inertial forces on the walls of circular and rectangular tanks.

15.7.6.2.2 Sloshing Sloshing of the stored liquid shall be taken into account in the seismic design of tanks and vessels in accordance with the following requirements:

(a) The height of the sloshing liquid, δ_s, above the product design height shall be computed using Equation (15.7-13):

$$\delta_s = 0.42 D_i I_e S_{ac} \tag{15.7-13}$$

For cylindrical tanks, D_i shall be the inside diameter of the tank; for rectangular tanks, D_i shall be replaced by the longitudinal plan dimension of the tank, L, for the direction under consideration.

(b) For tanks in Risk Category IV, the Importance Factor, I_e, used for freeboard determination only, shall be taken as 1.0.

(c) For tanks in Risk Categories I, II, and III, the value of T_L used for freeboard determination is permitted to be set equal to 4 s. The value of the Importance Factor, I_e, used for freeboard determination for tanks in Risk Categories I, II, and III shall be determined from Table 1.5-1.

(d) The effects of sloshing shall be accommodated by means of one of the following:

1. A minimum freeboard in accordance with Table 15.7-3,
2. A roof and supporting structure designed to contain the sloshing liquid in accordance with Subsection (e),
3. Secondary containment is provided to control the product spill, or
4. For open-top tanks or vessels only, an overflow spillway around the tank or vessel perimeter.

EXCEPTION: No minimum freeboard is required for open-top tanks where the following conditions are met:

1. Contained fluid is not toxic, explosive, or highly toxic and has been approved by the Authority Having Jurisdiction as acceptable for product spill.
2. Site-specific product spill prevention, control, and countermeasure plan (SPCC) has been developed and approved by the Authority Having Jurisdiction to properly handle resulting spill. The SPCC shall account for proper site drainage, infiltration, foundation scour, and protection of adjacent facilities from sloshing spill.

(e) If the sloshing is restricted because the freeboard is less than the computed sloshing height, then the roof and supporting structure shall be designed for an equivalent hydrostatic head equal to the computed sloshing height less the freeboard. Also, the design of the tank shall use the confined portion of the convective (sloshing) mass as an additional impulsive mass.

Table 15.7-3. Minimum Required Freeboard.

	Risk Category		
Value of S_{DS}	I or II	III	IV
$S_{DS} < 0.33g$	Not required	Not required	δ_s
$S_{DS} \geq 0.33g$	Not required	$0.7\delta_s$	δ_s

15.7.6.2.3 Equipment and Attached Piping Equipment, piping, and walkways or other appurtenances attached to the structure shall be designed to accommodate the displacements imposed by seismic forces. For piping attachments, see Section 15.7.4.

15.7.6.2.4 Internal Elements The attachments of internal equipment and accessories that are attached to the primary liquid or pressure retaining shell or bottom or that provide structural support for major elements (e.g., a column supporting the roof rafters) shall be designed for the lateral loads caused by the sloshing liquid, in addition to the inertial forces, by a substantiated analysis method.

15.7.6.2.5 Sliding Resistance The transfer of the total lateral shear force between the tank or vessel and the subgrade shall be considered as follows.

(a) For flat-bottom steel tanks, the overall horizontal seismic shear force is permitted to be resisted by friction between the tank bottom and the foundation or subgrade. Storage tanks shall be designed such that sliding does not occur where the tank is full of stored product. The maximum calculated seismic base shear, V, shall not exceed

$$V < W\tan 30° \tag{15.7-14}$$

(b) W shall be determined using the effective seismic weight of the tank, roof, and contents after reduction for coincident vertical earthquake. Lower values of the friction factor shall be used if the design of the tank bottom to supporting foundation does not justify the friction value given by Equation (15.7-14) (e.g., leak detection membrane beneath the bottom with a lower friction factor, smooth bottoms, etc.). Alternatively, the friction factor is permitted to be determined by testing in accordance with Section 11.1.4.

(c) No additional lateral anchorage is required for steel tanks designed in accordance with reference documents.

@seismicisolation
@seismicisolation

(d) The lateral shear transfer behavior for special tank configurations (e.g., shovel bottoms, highly crowned tank bottoms, or tanks on grillage) can be unique and is beyond the scope of this standard.

15.7.6.2.6 Local Shear Transfer Local transfer of the shear from the roof to the wall and the wall of the tank into the base shall be considered. For cylindrical tanks and vessels, the peak local tangential shear per unit length shall be calculated as

$$v_{\max} = \frac{2\ V}{\pi D} \qquad (15.7\text{-}15)$$

(a) Tangential shear in flat-bottom steel tanks shall be transferred through the welded connection to the steel bottom. This transfer mechanism is deemed acceptable for steel tanks designed in accordance with the reference documents where $S_{DS} < 1.0g$.
(b) For concrete tanks with a sliding base where the lateral shear is resisted by friction between the tank wall and the base, the friction coefficient value used for design shall not exceed tan 30°.
(c) Fixed-base or hinged-base concrete tanks transfer the horizontal seismic base shear shared by membrane (tangential) shear and radial shear into the foundation. For anchored flexible-base concrete tanks, most of the base shear is resisted by membrane (tangential) shear through the anchoring system, with only insignificant vertical bending in the wall. The connection between the wall and the floor shall be designed to resist the maximum tangential shear.

15.7.6.2.7 Pressure Stability For steel tanks, the internal pressure from the stored product stiffens thin cylindrical shell structural elements subjected to membrane compression forces. This stiffening effect is permitted to be considered in resisting seismically induced compressive forces if they are permitted by the reference document or the Authority Having Jurisdiction.

15.7.6.2.8 Shell Support Steel tanks resting on concrete ringwalls or slabs shall have a uniformly supported annulus under the shell. Uniform support shall be provided by one of the following methods:

(a) Shimming and grouting the annulus;
(b) Using fiberboard or other suitable padding;
(c) Using butt-welded bottom or annular plates resting directly on the foundation; or
(d) Using closely spaced shims (without structural grout), provided the localized bearing loads are considered in the tank wall and foundation to prevent local crippling and spalling.

Mechanically anchored tanks shall be shimmed and grouted. Local buckling of the steel shell for the peak compressive force caused by operating loads and seismic overturning shall be considered.

15.7.6.2.9 Repair, Alteration, or Reconstruction Repairs, modifications, or reconstruction (i.e., cut down and re-erect) of a tank or vessel shall conform to industry standard practice and this standard. For welded steel tanks storing liquids, see API 653 and the applicable reference document listed in Chapter 23. Tanks that are relocated shall be reevaluated for the seismic loads at the new site and the requirements of new construction in accordance with the appropriate reference document and this standard.

15.7.7 Water Storage and Water Treatment Tanks and Vessels

15.7.7.1 Welded Steel Welded steel water storage tanks and vessels shall be designed in accordance with the seismic requirements of AWWA D100, with the following exception:

(a) The seismic design ground motion values shall be determined according to Section 11.4(b). Modify AWWA D100, Section 13.5.4.4, as follows:
13.5.4.4 Freeboard. Sloshing shall be considered in determining the freeboard above the MOL. Freeboard is defined as the distance from the MOL to the lowest level of roof framing. The freeboard provided shall meet the requirements of Table 29. The sloshing wave height . . . .

15.7.7.2 Bolted Steel Bolted steel water storage structures shall be designed in accordance with the seismic requirements of AWWA D103, with the following exceptions:

(a) The seismic design ground motion values shall be determined according to Section 11.4.
(b) For Type 6 tanks, the overturning ratio, J, as determined using AWWA D103, Equation (14-32); shall not exceed 0.785.

15.7.7.3 Reinforced and Prestressed Concrete Reinforced and prestressed concrete tanks shall be designed in accordance with the seismic requirements of AWWA D110, AWWA D115, or ACI 350.3, except that the Importance Factor, I_e, shall be determined according to Section 15.4.1.1; the response modification coefficient, R, shall be taken from Table 15.4-2; the seismic design ground motion values shall be determined according to Section 11.4; and the design input forces for strength design procedures shall be determined using the procedures of ACI 350.3, except that S_{ac} shall be substituted for C_c in ACI 350.3, Section 9.4.2, using Equations (15.7-10) for $T_c \le T_L$ and (15.7-11) for $T_c > T_L$ from Section 15.7.6.1.

15.7.7.4 Corrugated Steel Corrugated steel water storage tanks, except those assigned to Risk Category I, shall meet the requirements of Sections 15.7.1 through 15.7.6 and the following requirements:

(a) Component allowable stresses and materials shall be in accordance with AWWA D103 for the hot-rolled steel elements of the tank. Minimum thicknesses per AWWA D103 shall not apply.
(b) Component stresses and materials shall be in accordance with AISI S100 for the cold-formed steel elements and connections of the tank.
(c) Vertical elements shall be added to the tank shell to resist compressive seismic forces. The buckling capacity of the vertical elements shall be determined using AISC 360 for hot-rolled steel elements or AISI S100 for cold-formed steel elements.
(d) The base shear and overturning moment shall be calculated as if the tank and the entire contents act as an impulsive mass using Equation (15.7-5). The convective mass shall be set equal to zero in Equation (15.7-6).
(e) Tank sliding, relative to the foundation, shall be resisted by embedment of the tank shell in the foundation.

@seismicisolation

Alternatively, the shell is permitted to be confined by a concrete curb designed to transfer the base shear forces from the tank to the foundation.

(f) The tank shall be mechanically anchored to the foundation to resist seismic uplift.

15.7.8 Petrochemical and Industrial Tanks and Vessels Storing Liquids

15.7.8.1 Welded Steel Welded steel flat-bottom, ground-supported petrochemical tanks, industrial tanks, and vessels storing liquids under an internal pressure less than or equal to 2.5 psig (17.2 kPa g) shall be designed in accordance with the seismic requirements of API 650. Welded steel flat-bottom, ground-supported petrochemical tanks, industrial tanks, and vessels storing liquids under an internal pressure greater than 2.5 psig (17.2 kPa g) and less than or equal to 15 psig (104.4 kPa g) shall be designed in accordance with the seismic requirements of API 620.

15.7.8.2 Bolted Steel Bolted steel tanks are used for storage of production liquids. API 12B covers the material, design, and erection requirements for vertical, cylindrical, and above-ground bolted tanks in nominal capacities of 100 barrels (15.9 m^3) to 10,000 barrels (1590 m^3) for production service. Unless required by the Authority Having Jurisdiction, these temporary structures need not be designed for seismic loads. If design for seismic load is required, the loads are permitted to be adjusted for the temporary nature of the anticipated service life.

15.7.8.3 Reinforced and Prestressed Concrete Reinforced concrete tanks for the storage of petrochemical and industrial liquids shall be designed in accordance with the force requirements of Section 15.7.7.3.

15.7.8.4 Corrugated Steel Corrugated steel petroleum and industrial liquid storage tanks, except those assigned to Risk Category I, shall meet the requirements of Section 15.7.7.4.

15.7.8.5 Reinforced Thermoset Plastic and Fiber-Reinforced Plastic Reinforced thermoset plastic and fiber-reinforced plastic tanks shall be designed in accordance with the requirements of ASME RTP-1, with the following exceptions:

(a) The seismic design ground motion values shall be determined according to Section 11.4.

(b) The seismic design base shear and overturning moment shall be determined using the seismic provisions of API 650, Annex E.

(c) ASME RTP-1, Nonmandatory Appendix NM-3, shall not be used.

(d) Where anchors in concrete or masonry are required to resist seismic forces, anchorage shall be in accordance with Section 15.4.9.

15.7.9 Ground-Supported Storage Tanks for Granular Materials

15.7.9.1 General The intergranular behavior of the material shall be considered in determining effective mass and load paths, including the following behaviors:

(a) Increased lateral pressure (and the resulting hoop stress) caused by loss of the intergranular friction of the material during seismic shaking;

(b) Increased hoop stresses generated from temperature changes in the shell after the material has been compacted; and

(c) Intergranular friction, which can transfer seismic shear directly to the foundation.

15.7.9.2 Lateral Force Determination The lateral forces for tanks and vessels storing granular materials at grade shall be determined by the requirements and accelerations for short-period structures (i.e., S_{DS}).

15.7.9.3 Force Distribution to Shell and Foundation

15.7.9.3.1 Increased Lateral Pressure The increase in lateral pressure on the tank wall shall be added to the static design lateral pressure but shall not be used in the determination of pressure stability effects on the axial buckling strength of the tank shell.

15.7.9.3.2 Effective Mass A portion of a stored granular mass acts with the shell (the effective mass). The effective mass is related to the physical characteristics of the product, the height-to-diameter ratio (H/D) of the tank, and the intensity of the seismic event. The effective mass shall be used to determine the shear and overturning loads resisted by the tank.

15.7.9.3.3 Effective Density The effective density factor (that part of the total stored mass of product that is accelerated by the seismic event) shall be determined in accordance with ACI 313.

15.7.9.3.4 Lateral Sliding For granular storage tanks that have a steel bottom and are supported such that friction at the bottom-to-foundation interface can resist lateral shear loads, no additional anchorage to prevent sliding is required. For tanks without steel bottoms (i.e., the material rests directly on the foundation), shear anchorage shall be provided to prevent sliding.

15.7.9.3.5 Combined Anchorage Systems If separate anchorage systems are used to prevent overturning and sliding, the relative stiffness of the systems shall be considered in determining the load distribution.

15.7.9.4 Welded Steel Structures Welded steel granular storage structures shall be designed in accordance with the seismic requirements of this standard. Component allowable stresses and materials shall be per AWWA D100, except that the allowable circumferential membrane stresses and material requirements in API 650 shall apply.

15.7.9.5 Bolted Steel Structures Bolted steel granular storage structures shall be designed in accordance with the seismic requirements of this section. Component allowable stresses and materials shall be per AWWA D103.

15.7.9.6 Reinforced Concrete Structures Reinforced concrete structures for the storage of granular materials shall be designed in accordance with the seismic force requirements of this standard and the requirements of ACI 313.

15.7.9.7 Prestressed Concrete Structures Prestressed concrete structures for the storage of granular materials shall be designed in accordance with the seismic force requirements of this standard and the requirements of ACI 313.

15.7.10 Elevated Tanks and Vessels for Liquids and Granular Materials

15.7.10.1 General This section applies to tanks, vessels, bins, and hoppers that are elevated above grade and where the supporting tower is an integral part of the structure. Tanks and vessels that are supported by another structure are considered mechanical equipment and shall be designed in accordance with Section 15.3.

@seismicisolation

Elevated tanks shall be designed for the force and displacement requirements of the applicable reference document or Section 15.4.

15.7.10.2 Effective Mass The design of the supporting tower or pedestal, anchorage, and foundation for seismic overturning shall assume that the stored material is a rigid mass acting at the volumetric center of gravity. The effects of fluid–structure interaction are permitted to be considered in determining the forces, effective period, and mass centroids of the system if the following requirements are met:

(a) The sloshing period, T_c, is greater than $3T$, where T is the natural period of the tank with confined liquid (rigid mass) and supporting structure, and
(b) The sloshing mechanism (i.e., the percentage of convective mass and centroid) is determined for the specific configuration of the container by detailed fluid–structure interaction analysis or testing.

Soil–structure interaction is permitted to be included in determining T, provided the requirements of Chapter 19 are met.

15.7.10.3 P-Delta Effects The lateral drift of the elevated tank shall be considered as follows:

(a) The design drift, as determined by an elastic analysis, shall be increased by the factor C_d/I_e for evaluating the additional load in the support structure.
(b) The base of the tank shall be assumed to be fixed rotationally and laterally.
(c) Deflections caused by bending, axial tension, or compression shall be considered. For pedestal tanks with a height-to-diameter ratio less than 5, shear deformations of the pedestal shall be considered.
(d) The dead load effects of roof-mounted equipment or platforms shall be included in the analysis.
(e) Initial tilt need not be considered in the P-delta analysis if constructed within the plumbness tolerances specified by the reference document.

15.7.10.4 Transfer of Lateral Forces into Support Tower For post-supported tanks and vessels that are cross-braced:

(a) The bracing shall be installed in such a manner as to provide uniform resistance to the lateral load (e.g., pre-tensioning or tuning to attain equal sag).
(b) The additional load in the brace caused by the eccentricity between the post-to-tank attachment and the line of action of the bracing shall be included.
(c) Eccentricity of compression strut line of action (elements that resist the tensile pull from the bracing rods in the seismic force-resisting systems) with their attachment points shall be considered.
(d) The connection of the post or leg with the foundation shall be designed to resist both the vertical and lateral resultant from the yield load in the bracing, assuming that the direction of the lateral load is oriented to produce the maximum lateral shear at the post-to-foundation interface. Where multiple rods are connected to the same location, the anchorage shall be designed to resist the concurrent tensile loads in the braces.

15.7.10.5 Evaluation of Structures Sensitive to Buckling Failure Shell structures that support substantial loads may exhibit a primary mode of failure from localized or general buckling of the support pedestal or skirt caused by seismic loads. Such structures may include single-pedestal water towers, skirt-supported process vessels, and similar single-member towers. Where the structural assessment concludes that buckling of the support is the governing primary mode of failure, structures specified in this standard to be designed to Subsections (a) and (b) and those that are assigned as Risk Category IV shall be designed to resist the seismic forces as follows:

(a) The seismic response coefficient for this evaluation shall be in accordance with Section 12.8.1.1 of this standard, with I_e/R set equal to 1.0. Soil–structure and fluid–structure interactions are permitted to be used in determining the structural response. Vertical or orthogonal combinations need not be considered.
(b) The resistance of the structure shall be defined as the critical buckling resistance of the element, that is, a factor of safety set equal to 1.0.

15.7.10.6 Welded Steel Water Storage Structures Welded steel elevated water storage structures shall be designed and detailed in accordance with the seismic requirements of AWWA D100, with the structural height limits imposed by Table 15.4-2.

15.7.10.7 Concrete Pedestal (Composite) Tanks Concrete pedestal (composite) elevated water storage structures shall be designed in accordance with the requirements of AWWA D107, except that the seismic design ground motion values shall be determined according to Section 11.4.

15.7.11 Boilers and Pressure Vessels

15.7.11.1 General Attachments to the pressure boundary, supports, and seismic force-resisting anchorage systems for boilers and pressure vessels shall be designed to meet the force and displacement requirements of Section 15.3 or 15.4 and the additional requirements of this section. Boilers and pressure vessels categorized as Risk Category III or IV shall be designed to meet the force and displacement requirements of Section 15.3 or 15.4.

15.7.11.2 ASME Boilers and Pressure Vessels Boilers or pressure vessels designed and constructed in accordance with the ASME *Boiler and Pressure Vessel Code* (BPVC) shall be deemed to meet the requirements of this section, provided the force and displacement requirements of Section 15.3 or 15.4 are used, with appropriate scaling of the force and displacement requirements to the working stress design basis.

15.7.11.3 Attachments of Internal Equipment and Refractory Attachments to the pressure boundary for internal and external ancillary components (refractory, cyclones, trays, etc.) shall be designed to resist the seismic forces specified in this standard to safeguard against rupture of the pressure boundary. Alternatively, the element attached is permitted to be designed to fail before damaging the pressure boundary, provided the consequences of the failure do not place the pressure boundary in jeopardy. For boilers or vessels containing liquids, the effect of sloshing on the internal equipment shall be considered if the equipment can damage the integrity of the pressure boundary.

15.7.11.4 Coupling of Vessel and Support Structure Where the mass of the operating vessel or vessels supported is greater than 20% of the total mass of the combined structure, the structure and vessel designs shall consider the effects of

@seismicisolation

dynamic coupling between each other. Coupling with adjacent, connected structures such as multiple towers shall be considered if the structures are interconnected with elements that transfer loads from one structure to the other.

15.7.11.5 Effective Mass Fluid–structure interaction (sloshing) shall be considered in determining the effective mass of the stored material, provided sufficient liquid surface exists for sloshing to occur and that T_c is greater than $3T$. Changes to or variations in material density with pressure and temperature shall be considered.

15.7.11.6 Other Boilers and Pressure Vessels Boilers and pressure vessels designated as being in Risk Category IV, but not designed and constructed in accordance with the requirements of the ASME BPVC, shall meet the following requirements.

The seismic loads, in combination with other service loads and appropriate environmental effects, shall not exceed the material strength shown in Table 15.7-4.

Consideration shall be made to mitigate seismic impact loads for boiler or vessel elements constructed of nonductile materials or vessels operated in such a way that material ductility is reduced (e.g., low-temperature applications).

15.7.11.7 Supports and Attachments for Boilers and Pressure Vessels Attachments to the pressure boundary and support for boilers and pressure vessels shall meet the following requirements:

(a) Attachments and supports transferring seismic loads shall be constructed of ductile materials suitable for the intended application and environmental conditions.
(b) Anchorage shall be in accordance with Section 15.4.9, whereby the anchor embedment into the concrete is designed to develop the steel strength of the anchor in tension. The steel strength of the anchor in tension shall be determined in accordance with ACI 318, Equation (17.6.1.2). The anchor shall have a minimum gauge length of eight diameters. The load combinations including overstrength of Section 12.4.3 are not to be used to size the anchor bolts for tanks and horizontal and vertical vessels.
(c) Seismic supports and attachments to structures shall be designed and constructed so that the support or attachment remains ductile throughout the range of reversing seismic lateral loads and displacements.
(d) Vessel attachments shall consider the potential effect on the vessel and the support for uneven vertical reactions based on variations in relative stiffness of the support members, dissimilar details, nonuniform shimming, or irregular supports. Uneven distribution of lateral forces shall consider the relative distribution of the resisting elements, the behavior of the connection details, and vessel shear distribution.

Table 15.7-4. Maximum Material Strength.

Material	Minimum Ratio F_u/F_y	Max. Material Strength of Vessel Material (%)	Max. Material Strength of Threaded Material (%)[a]
Ductile (e.g., steel, aluminum, copper)	1.33[b]	90[c]	70[c]
Semiductile	1.2[d]	70[c]	50[c]
Nonductile (e.g., cast iron, ceramics, fiberglass)	N/A	25[e]	20[e]

[a] Threaded connection to vessel or support system.
[b] Minimum 20% elongation per the ASTM material specification.
[c] Based on material minimum specified yield strength.
[d] Minimum 15% elongation per the ASTM material specification.
[e] Based on material minimum specified tensile strength.
Note: N/A = not applicable.

The requirements of Sections 15.4 and 15.7.10.5 shall also be applicable to this section.

15.7.12 Liquid and Gas Spheres

15.7.12.1 General Attachments to the pressure or liquid boundary, supports, and seismic force-resisting anchorage systems for liquid and gas spheres shall be designed to meet the force and displacement requirements of Section 15.3 or 15.4 and the additional requirements of this section. Spheres categorized as Risk Category III or IV shall themselves be designed to meet the force and displacement requirements of Section 15.3 or 15.4.

15.7.12.2 ASME Spheres Spheres designed and constructed in accordance with Section VIII of the ASME BPVC shall be deemed to meet the requirements of this section, provided the force and displacement requirements of Section 15.3 or 15.4 are used with appropriate scaling of the force and displacement requirements to the working stress design basis.

15.7.12.3 Attachments of Internal Equipment and Refractory Attachments to the pressure or liquid boundary for internal and external ancillary components (refractory, cyclones, trays, etc.) shall be designed to resist the seismic forces specified in this standard to safeguard against rupture of the pressure boundary. Alternatively, the element attached to the sphere could be designed to fail before damaging the pressure or liquid boundary, provided the consequences of the failure do not place the pressure boundary in jeopardy. For spheres containing liquids, the effect of sloshing on the internal equipment shall be considered if the equipment can damage the pressure boundary.

15.7.12.4 Effective Mass Fluid–structure interaction (sloshing) shall be considered in determining the effective mass of the stored material, provided sufficient liquid surface exists for sloshing to occur and T_c is greater than $3T$. Changes to or variations in fluid density shall be considered.

15.7.12.5 Post- and Rod-Supported Spheres For post-supported spheres that are cross-braced,

(a) The requirements of Section 15.7.10.4 shall also be applicable to this section.
(b) The stiffening effect (reduction in lateral drift) from pretensioning of the bracing shall be considered in determining the natural period.
(c) The slenderness and local buckling of the posts shall be considered.
(d) Local buckling of the sphere shell at the post attachment shall be considered.
(e) For spheres storing liquids, bracing connections shall be designed and constructed to develop the minimum published yield strength of the brace. For spheres storing gas vapors only, bracing connection shall be designed for Ω_0 times the maximum design load in the brace. Lateral

@seismicisolation
@seismicisolation

bracing connections directly attached to the pressure or liquid boundary are prohibited.

15.7.12.6 Skirt-Supported Spheres For skirt-supported spheres, the following requirements shall apply:

(a) The requirements of Section 15.7.10.5 shall also apply.
(b) The local buckling of the skirt under compressive membrane forces caused by axial load and bending moments shall be considered.
(c) Penetration of the skirt support (manholes, piping, etc.) shall be designed and constructed to maintain the strength of the skirt without penetrations.

15.7.13 Refrigerated Gas Liquid Storage Tanks and Vessels

15.7.13.1 General Tanks and facilities for the storage of liquefied hydrocarbons and refrigerated liquids shall meet the requirements of this standard. Low-pressure welded steel flat-bottom, ground-supported storage tanks for liquefied hydrocarbon gas (e.g., liquefied petroleum gas or butane) and refrigerated liquids (e.g., ammonia) shall be designed in accordance with the requirements of Section 15.7.8 and API 620.

15.7.14 Horizontal, Saddle-Supported Vessels for Liquid or Vapor Storage

15.7.14.1 General Horizontal vessels supported on saddles (sometimes referred to as "blimps") shall be designed to meet the force and displacement requirements of Section 15.3 or 15.4.

15.7.14.2 Effective Mass Changes to or variations in material density shall be considered. The design of the supports, saddles, anchorage, and foundation for seismic overturning shall assume that the material stored is a rigid mass acting at the volumetric center of gravity.

15.7.14.3 Vessel Design Unless a more rigorous analysis is performed,

(a) Horizontal vessels with a length-to-diameter ratio of 6 or more are permitted to be assumed to be a simply supported beam spanning between the saddles for determining the natural period of vibration and global bending moment.
(b) For horizontal vessels with a length-to-diameter ratio of less than 6, the effects of "deep beam shear" shall be considered where determining the fundamental period and stress distribution.
(c) Local bending and buckling of the vessel shell at the saddle supports caused by seismic load shall be considered. The stabilizing effects of internal pressure shall not be considered to increase the buckling resistance of the vessel shell.
(d) If the vessel is a combination of liquid and gas storage, the vessel and supports shall be designed (both with and without gas pressure acting assume that piping has ruptured and pressure does not exist).

15.8 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

See Chapter 23 for the list of consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

CHAPTER 16
NONLINEAR RESPONSE HISTORY ANALYSIS

16.1 GENERAL REQUIREMENTS

16.1.1 Scope It shall be permitted to use nonlinear response history analysis, in accordance with the requirements of this chapter, to demonstrate acceptable strength, stiffness, and ductility to resist maximum considered earthquake (MCE_R) shaking with acceptable performance. When nonlinear response history analysis is performed, the design shall also satisfy the requirements of Section 16.1.2. Nonlinear response history analysis shall include the effects of horizontal motion, and where required by Section 16.1.3, vertical motion. Documentation of the design and analysis shall be prepared in accordance with Section 16.1.4. Ground motion acceleration histories shall be selected and modified in accordance with the procedures of Section 16.2. The structure shall be modeled and analyzed in accordance with the criteria in Section 16.3. Analysis results shall meet the acceptance criteria of Section 16.4. Independent structural design review shall be performed in accordance with the requirements of Section 16.5.

16.1.2 Linear Analysis In addition to nonlinear response history analysis, a linear analysis in accordance with one of the applicable procedures of Chapter 12 shall also be performed. The structure's design shall meet all applicable criteria of Chapter 12.

EXCEPTIONS:

1. For Risk Category I, II, and III structures, Sections 12.12.1 and 12.12.5 do not apply to the linear analysis. Where mean computed drifts from the nonlinear analyses exceed 150% of the permissible story drifts per Section 12.12.1, deformation-sensitive nonstructural components shall be designed for 2/3 of these mean drifts.
2. The overstrength factor, Ω_0, is permitted to be taken as 1.0 for the seismic load effects of Section 12.4.3.
3. The redundancy factor, ρ, is permitted to be taken as 1.0.
4. Where accidental torsion is explicitly modeled in the nonlinear analysis, it shall be permitted to take the value of A_x as unity in the Chapter 12 analysis.

16.1.3 Vertical Response Analysis Nonlinear response history analysis shall explicitly include the effects of vertical response where any of the following occur:

1. Vertical elements of the gravity force-resisting system are discontinuous.
2. For nonbuilding structures, when Chapter 15 requires consideration of vertical earthquake effects.

16.1.4 Documentation Before performing the nonlinear analysis, project-specific design criteria shall be approved by the independent structural design reviewer(s) and the Authority Having Jurisdiction. The project-specific criteria shall identify the following:

1. The selected seismic and gravity force-resisting systems and procedures used in the structural design.
2. Geotechnical parameters including soil characteristics, recommended foundation types, design parameters, seismic hazard evaluation, target spectra, and selection and scaling of acceleration histories.
3. Design loading, including gravity and environmental loads.
4. Analytical modeling approach and assumptions, including software to be used, definition of mass, identification of force-controlled and deformation-controlled behaviors, description of which component actions are modeled elastically and inelastically, expected material properties, basis for hysteretic component modeling, component initial stiffness assumptions, joint stiffness assumptions, diaphragm modeling, damping, and procedure for modeling foundation–soil interaction.
5. Summaries of laboratory test and other applicable data used to justify the hysteretic component modeling or used to justify acceptable structural performance.
6. Specific acceptance criteria values used for evaluating performance of elements of the seismic force-resisting system. Associated documentation shall also include identification of component failure modes deemed indicative of collapse.
7. Where drifts exceed 150% of the values permitted in Section 12.12, the criteria used to demonstrate acceptable deformation compatibility of components of the gravity force-resisting system.

Following completion of the analysis process, the following documentation shall be prepared and presented to the independent structural design reviewer(s) and the Authority Having Jurisdiction:

1. Final geotechnical report, including soil shear strength, stiffness, and damping characteristics; recommended foundation types and design parameters; and seismic hazard evaluation, including both the target spectra and selection and scaling of ground motions.
2. Overall building dynamic behavior, including natural frequencies, mode shapes, and modal mass participation.
3. Key structural system response parameter results and comparisons with the acceptance criteria of Section 16.4.
4. Detailing of critical elements.

16.2 GROUND MOTIONS

16.2.1 Target Response Spectrum A target, 5%-damped, MCE_R response spectrum shall be developed using either the

@seismicisolation
@seismicisolation

procedures of Section 16.2.1.1 or Section 16.2.1.2. It shall be permitted to consider the effects of base slab averaging and foundation embedment in accordance with Chapter 19.

Where the effects of vertical earthquake shaking are included in the analysis, a target MCE_R vertical spectrum shall also be constructed.

16.2.1.1 Method 1 A single target response spectrum shall be developed, based on the requirements of either Section 11.4.6 or Section 11.4.7.

16.2.1.2 Method 2 Two or more site-specific target response spectra shall be developed. When this method is used, the following requirements shall be fulfilled, in addition to the other requirements of this chapter:

1. Two or more periods shall be selected, corresponding to those periods of vibration that significantly contribute to the inelastic dynamic response of the building in two orthogonal directions. In the selection of periods, lengthening of the elastic periods of the model shall be considered.
2. For each selected period, a target spectrum shall be created that either matches or exceeds the MCE_R value at that period. When developing the target spectrum, (1) site-specific disaggregation shall be performed to identify earthquake events that contribute most to the MCE_R ground motion at the selected period and (2) the target spectrum shall be developed to capture one or more spectral shapes for dominant magnitude and distance combinations revealed by the disaggregation.
3. The envelope of the target spectra shall not be less than 75% of the spectral values computed using Method 1 of Section 16.2.1.1, for all periods in the range specified in Section 16.2.3.1.
4. For each target response spectrum, a ground motion suite for response history analyses shall be developed and used in accordance with Sections 16.2.3 through 16.2.4. The acceptance criteria requirements of Section 16.4 shall be evaluated independently for each of the ground motion suites.

Variations on the procedures described in this section are permitted to be used when approved by the design review.

16.2.2 Ground Motion Selection A suite of not less than 11 ground motions shall be selected for each target spectrum. Ground motions shall consist of pairs of orthogonal horizontal ground motion components and, where vertical earthquake effects are considered, a single vertical ground motion component. Ground motions shall be selected from events within the same general tectonic regime and having generally consistent magnitudes and fault distances as those controlling the target spectrum and shall have a spectral shape similar to the target spectrum. For near-fault sites, as defined in Section 11.4.1, and other sites where MCE_R shaking can exhibit directionality and impulsive characteristics, the proportion of ground motions with near-fault and rupture directivity effects shall represent the probability that MCE_R shaking will exhibit these effects. Where the required number of recorded ground motions is not available, it shall be permitted to supplement the available records with simulated ground motions. Ground motion simulations shall be consistent with the magnitudes, source characteristics, fault distances, and site conditions controlling the target spectrum.

16.2.3 Ground Motion Modification Ground motions shall either be amplitude-scaled in accordance with the requirements of Section 16.2.3.2 or spectrally matched in accordance with the requirements of Section 16.2.3.3. Spectral matching shall not be used for near-fault sites unless the pulse characteristics of the ground motions are retained after the matching process has been completed.

16.2.3.1 Period Range for Scaling or Matching A period range shall be determined, corresponding to the vibration periods that contribute significantly to the building's lateral dynamic response. This period range shall have an upper bound, greater than or equal to twice the largest first-mode period in the principal horizontal directions of response, unless a lower value, not less than 1.5 times the largest first-mode period, is justified by dynamic analysis under MCE_R ground motions. The lower bound period shall be established such that the period range includes at least the number of elastic modes necessary to achieve 90% mass participation in each principal horizontal direction. The lower bound period shall not exceed 20% of the smallest first-mode period for the two principal horizontal directions of response. Where vertical response is considered in the analysis, the lower bound period used for modification of vertical components of ground motion need not be taken as less than the larger of 0.1 seconds, or the lowest period at which significant vertical mass participation occurs.

16.2.3.2 Amplitude Scaling For each horizontal ground motion pair, a maximum-direction spectrum shall be constructed from the two horizontal ground motion components. Each ground motion shall be scaled, with an identical scale factor applied to both horizontal components, such that the average of the maximum-direction spectra from all ground motions generally matches or exceeds the target response spectrum over the period range defined in Section 16.2.3.1. The average of the maximum-direction spectra from all the ground motions shall not fall below 90% of the target response spectrum for any period within the same period range. Where vertical response is considered in the analysis, the vertical component of each ground motion shall be scaled such that the average of the vertical response spectra envelops the target vertical response spectrum over the period range specified in Section 16.2.3.1.

16.2.3.3 Spectral Matching Each pair of ground motions shall be modified such that the average of the maximum-direction spectra for the suite equals or exceeds 110% of the target spectrum over the period range defined in Section 16.2.3.1. Where vertical response is considered in the analysis, the vertical component of each ground motion shall be spectrally matched to the target vertical response spectrum, such that the average of the matched spectra does not fall below the target vertical spectrum in the scaling range of Section 16.2.3.1.

16.2.4 Application of Ground Motions to the Structural Model Ground motions shall be applied to the supports of the structural model. For near-fault sites, as defined in Section 11.4.1, each pair of horizontal ground motion components representative of a nearby fault source shall be rotated to the fault-normal and fault-parallel directions of the causative fault and applied to the building in such orientation. For all other selected ground motions at near-fault sites, and for all ground motions at other sites, each pair of horizontal ground motion components shall be applied to the building at orthogonal orientations, such that the average (or mean) of the component response spectrum for the records applied in each direction is within ±10% of the mean of the component response spectra of all records applied for the period range specified in Section 16.2.3.1.

@seismicisolation
@seismicisolation

16.3 MODELING AND ANALYSIS

16.3.1 Modeling Mathematical models shall be three-dimensional and shall conform to the requirements of this section and Section 12.7. For structures that have subterranean levels, the structural model shall extend to the foundation level and ground motions shall be input at the foundation level. All elements that significantly affect seismic response when subjected to MCE_R ground motions shall be included. Modeling of element nonlinear hysteretic behavior shall be consistent with ASCE 41 or applicable laboratory test data. Test data shall not be extrapolated beyond tested deformation levels. Degradation in element strength or stiffness shall be included in the hysteretic models unless it can be demonstrated that response is not sufficient to produce these effects.

Analysis models shall be capable of representing the flexibility of floor diaphragms where this is significant to the structure's response. Diaphragms at horizontal and vertical discontinuities in lateral resistance shall be explicitly modeled in a manner that permits capturing the force transfers and resulting deformations.

16.3.2 Gravity Load The modeling of, and demands on, elements in the analysis model shall be determined considering earthquake effects acting in combination with expected gravity loads, both with and without live load. Gravity loads with live load shall be taken as $1.0D + 0.5L$, where L shall be taken as 80% of unreduced live loads that exceed $100\,lb/ft^2$ ($4.79\,kN/m^2$) and 40% of all other unreduced live loads. Gravity loads without live load shall be taken as $1.0D$.

EXCEPTION: Where the sum, over the entire structure, of the expected live load ($0.5L$), as defined above, does not exceed 25% of the total dead load, D, and the live load intensity, L_0, over at least 75% of the structure is less than 100 psf ($4.79\,kN/m^2$), the case without live load need not be considered.

16.3.3 P-Delta Effects P-delta effects considering the spatial distribution of gravity loads shall be included in the analysis.

16.3.4 Torsion Inherent eccentricity resulting from any offset in the centers of mass and stiffness at each level shall be accounted for in the analysis. In addition, where a Type 1 horizontal structural irregularly exists, as defined in Section 12.3.2.1, accidental eccentricity consisting of an assumed displacement of the center of mass each way from its actual location by a distance equal to 5% of the diaphragm dimension of the structure parallel to the direction of mass shift shall be considered. The required 5% displacement of the center of mass need not be applied in both orthogonal directions at the same time.

16.3.5 Damping Hysteretic energy dissipation of structural members shall be modeled directly. Additional inherent damping, not associated with inelastic behavior of elements, shall be modeled appropriate to the structure type and shall not exceed 2.5% equivalent viscous damping in the significant modes of response.

16.3.6 Explicit Foundation Modeling When soil spring and/or dashpot elements are included in the structural model, horizontal input ground motions shall be applied to the horizontal soil elements rather than being applied to the foundation directly.

16.4 ANALYSIS RESULTS AND ACCEPTANCE CRITERIA

Structures shall be demonstrated to meet the global acceptance criteria of Section 16.4.1 and the element-level acceptance criteria of Section 16.4.2.

The mean value of story drift, and element demand, Q_u, shall be used to evaluate acceptability.

EXCEPTION: Where a ground motion produces unacceptable response as permitted in Section 16.4.1.1, 120% of the median value, but not less than the mean value obtained from the suite of analyses producing acceptable response shall be used.

16.4.1 Global Acceptance Criteria

16.4.1.1 Unacceptable Response Unacceptable response to ground motion shall consist of any of the following:

1. Analytical solution fails to converge,
2. Predicted demands on deformation-controlled elements exceed the valid range of modeling,
3. Predicted demands on critical or ordinary force-controlled elements, as defined in Section 16.4.2, exceed the element capacity,
4. Predicted deformation demands on elements not explicitly modeled exceed the deformation limits at which the members are no longer able to carry their gravity loads,
5. Peak transient story drift ratio exceeds 150% of the permissible value of mean transient story drift, as per Section 16.4.1.2, or
6. For structures exceeding 240 ft (73m) in height, the residual story drift for any story exceeds a value of $0.015\,h_{sx}$.

Unacceptable response to ground motion shall not be permitted.

EXCEPTION: For Risk Category I and II structures, where spectral matching of ground motion is not used, not more than one motion shall be permitted to produce unacceptable response.

16.4.1.2 Transient Story Drift The mean transient story drift for all building heights, $\overline{\Delta}$ in ft (m), shall not exceed two times the limits of Table 12.12-1. Additionally, for structures exceeding 100 ft (30 m) in height, $\overline{\Delta}$ shall not exceed the value obtained from Equation (16.4-1):

$$\overline{\Delta} \le h_{sx}(4.71x10^{-2} - 7.14x10^{-5}h_n) \qquad (16.4\text{-}1)$$

$$\overline{\Delta} \le h_{sx}(4.71x10^{-2} - 2.34x10^{-4}h_n) \qquad (16.4\text{-}1.SI)$$

where h_n and h_{sx} are measured in ft (m). The value obtained from Equation (16.4-1) need not be taken less than $0.03\,h_n$.

The transient story drift ratio shall be computed as the absolute value of the largest difference of the deflections of vertically aligned points at the top and bottom of the story under consideration along any of the edges of the structure within a single response history analysis. For masonry shear wall structures, the limits of Table 12.12-1 applicable to masonry cantilever wall structures and other masonry wall structures shall not apply and these structures shall instead comply with the limits for other structures.

16.4.1.3 Residual Story Drift For structures exceeding 240 ft (73 m) in height, the mean residual story drift shall not exceed $0.01\,h_{sx}$, where residual story drift is taken as the maximum value of story drift in a structure at rest, following response to an earthquake motion.

16.4.2 Element-Level Acceptance Criteria All element actions shall be classified either as force-controlled or deformation-controlled, in accordance with ACI 318 for reinforced concrete elements or ASCE 41 for elements of other materials.

@seismicisolation
@seismicisolation

For each element action, the quantity, Q_u, shall be computed. Q_u shall be taken as the mean value of the response parameter of interest obtained from the suite of analyses.

Force-controlled actions shall be evaluated for acceptability in accordance with Section 16.4.2.1. Deformation-controlled actions shall be evaluated for acceptability in accordance with Section 16.4.2.2. Where required by Section 16.4.2.1, element actions shall be categorized as Critical, Ordinary, or Noncritical.

16.4.2.1 Force-Controlled Actions Force-controlled actions shall satisfy Equation (16.4-1) and (16.4-2):

$$(1.2 + 0.12S_{MS})D + 0.5L + 1.3I_e(Q_u - Q_{ns}) \le \phi BR_n \quad (16.4\text{-}1)$$

$$(0.9 - 0.12S_{MS})D + 1.3I_e(Q_u - Q_{ns}) \le \phi BR_n \quad (16.4\text{-}2)$$

where D and L are as defined in Section 16.3.2, S_{MS} is the site-adjusted Maximum Considered Earthquake Spectral Acceleration at a period of 0.2 seconds; I_e is the Importance Factor prescribed in Section 1.5.1; Q_u is the mean value of the demand computed from the suite of analyses; Q_{ns} is the portion of the demand caused by loads other than seismic; R_n is the nominal strength specified by the applicable material standard. The resistance factor ϕ for Critical elements shall be taken as the value specified by the applicable material standard. The resistance factor ϕ for Ordinary elements shall be taken as 0.9. The resistance factor ϕ for Noncritical elements shall be taken as 1.0. B is a factor to account for differences between expected strength R_{ne} and nominal resistance R_n. It is permitted to assign B a value of 1.0, or, alternatively, B can be taken as $0.9R_{ne}/R_n$, where R_{ne} is the expected strength of the element.

Where an industry standard referenced in Chapter 14 defines expected strength, that value shall be used. Where this is not defined, it shall be permitted to calculate expected strength as the nominal strength defined in industry standards, except that expected material properties as defined in ACI 318 for reinforced concrete elements and ASCE 41 for elements of other materials shall be used in lieu of specified values.

EXCEPTIONS:

1. Noncritical force-controlled actions that are modeled, including consideration of strength loss effects, need not satisfy Equations (16.4-1) or (16.4-2).
2. Force-controlled actions limited by formation of a yield mechanism, other than shear in structural walls, need only satisfy Equations (16.4-3) and (16.4-4):

$$(1.2 + 0.12S_{MS})D + 0.5L + 0.2S + E_{mc} \le \phi BR_n \quad (16.4\text{-}3)$$

$$(0.9 - 0.12S_{MS})D + E_{mc} \le \phi BR_n \quad (16.4\text{-}4)$$

   Where E_{mc} is the capacity-limited earthquake effect associated with developing the plastic capacity of yielding components, determined in accordance with the applicable material standard, or alternatively, determined by rational analysis considering expected material properties including strain hardening effects where applicable.
3. Where response to vertical earthquake shaking is directly included in the analysis, the first term in equations 16.4-1 through 16.4-4 can be taken as 1.2D (16.4-1 and 16.4-3) or 0.9D (16.4-2 and 16.4-4).

16.4.2.2 Deformation-Controlled Actions The valid range of modeling for deformation-controlled element actions shall be as established in the applicable material design standard. Where the material design standard does not specify the valid range of modeling, this parameter shall be established as the maximum value of the parameter at which the element model is capable of replicating the hysteretic behavior and load-carrying capability observed in laboratory testing of similar elements. Where suitable test data is not available, either the valid range of modeling of the deformation capacity specified in ACI 318 for reinforced concrete elements or the maximum deformation parameter as specified by ASCE 41 for elements of other materials shall be used. It shall be permitted to extend the valid range of modeling for an element beyond these deformations if the element strength and stiffness are degraded to negligible values once these deformations are reached.

16.4.2.3 Elements of the Gravity Force-Resisting System Elements that are not part of the seismic force-resisting system shall be demonstrated to be capable of supporting gravity loads using the mean building displacements from the suite of nonlinear response history analyses.

16.5 DESIGN REVIEW

An independent structural design review shall be performed in accordance with the requirements of this section. Upon completion of the review, the reviewer(s) shall provide the Authority Having Jurisdiction and the registered design professional with a letter attesting to:

1. Scope of review performed,
2. Whether the reviewer(s) concur with the analysis and its applicability to the design,
3. Conformance of the design to applicable requirements of the standard, and
4. Any items relating to the design or analysis that require further resolution by the Authority Having Jurisdiction.

16.5.1 Reviewer Qualifications Reviewer(s) shall consist of one or more individuals acceptable to the Authority Having Jurisdiction and possessing knowledge of the following items:

1. The requirements of this standard and the standards referenced herein, as they pertain to design of the type of structure under consideration.
2. Selection and scaling of ground motions for use in nonlinear response history analysis.
3. Analytical structural modeling for use in nonlinear response history analysis, including use of laboratory tests in the creation and calibration of the structural analysis models, and including knowledge of soil–structure interaction if used in the analysis or the treatment of ground motions.
4. Behavior of structural systems, of the type under consideration, when subjected to earthquake loading.

At least one reviewer shall be a registered design professional.

16.5.2 Review Scope The scope of review shall include the items identified in Section 16.1.4, as well as the associated project documentation that demonstrates conformance to the design criteria.

16.6 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

See Chapter 23 for the list of consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

@seismicisolation

CHAPTER 17
SEISMIC DESIGN REQUIREMENTS FOR SEISMICALLY ISOLATED STRUCTURES

17.1 GENERAL

Every seismically isolated structure and every portion thereof shall be designed and constructed in accordance with the requirements of this section and the applicable requirements of this standard.

17.1.1 Definitions The following definitions only apply to the seismically isolated structure provisions of Chapter 17 and are in addition to the definitions presented in Chapter 11.

BASE LEVEL: The first level of the isolated structure above the isolation interface.

DISPLACEMENT RESTRAINT SYSTEM: A collection of structural elements that limits lateral displacement of seismically isolated structures caused by the maximum considered earthquake.

EFFECTIVE DAMPING: The value of equivalent viscous damping corresponding to energy dissipated during cyclic response of the isolation system.

EFFECTIVE STIFFNESS: The value of the lateral force in the isolation system, or an element thereof, divided by the corresponding lateral displacement.

ISOLATION INTERFACE: The boundary between the upper portion of the structure, which is isolated, and the lower portion of the structure, which moves rigidly with the ground.

ISOLATION SYSTEM: The collection of structural elements that includes all individual isolator units, all structural elements that transfer force between elements of the isolation system, and all connections to other structural elements. The isolation system also includes the wind-restraint system, energy-dissipation devices, and/or the displacement restraint system if such systems and devices are used to meet the design requirements of this chapter.

ISOLATOR UNIT: A horizontally flexible and vertically stiff structural element of the isolation system that permits large lateral deformations under design seismic load. An isolator unit is permitted to be used either as part of, or in addition to, the weight-supporting system of the structure.

MAXIMUM DISPLACEMENT: The maximum lateral displacement, excluding additional displacement caused by actual and accidental torsion, required for design of the isolation system. The maximum displacement is to be computed separately using upper bound and lower bound properties.

SCRAGGING: Cyclic loading or working of rubber products, including elastomeric isolators, to effect a reduction in stiffness properties, a portion of which is recovered over time.

TOTAL MAXIMUM DISPLACEMENT: The total maximum lateral displacement, including additional displacement caused by actual and accidental torsion, required for the verification of the stability of the isolation system or elements thereof, design of structure separations, and vertical load testing of isolator unit prototypes. The total maximum displacement is to be computed separately using upper bound and lower bound properties.

WIND-RESTRAINT SYSTEM: The collection of structural elements that provides restraint of the seismically isolated structure for wind loads. The wind-restraint system is permitted to be either an integral part of isolator units or a separate device.

17.1.2 Symbols Symbols presented in this section only apply to the seismically isolated structure provisions of Chapter 17 and are in addition to the symbols presented in Chapter 11.

b = Shortest plan dimension of the structure, ft (mm) measured perpendicular to d

B_M = Numerical coefficient as set forth in Table 17.5-1, for effective damping equal to β_M

C_{vx} = Vertical distribution factor

d = Longest plan dimension of the structure, ft (mm) measured perpendicular to b

D_M = Maximum displacement, in. (mm) at the center of rigidity of the isolation system in the direction under consideration, as prescribed by Equation (17.5-1)

D'_M = Maximum displacement, in. (mm) at the center of rigidity of the isolation system in the direction under consideration, as prescribed by Equation (17.6-1)

D_{TM} = Total maximum displacement, in. (mm) of an element of the isolation system including both translational displacement at the center of rigidity and the component of torsional displacement in the direction under consideration, as prescribed by Equation (17.5-3)

e = Actual eccentricity, ft (mm) measured in plan between the center of mass of the structure above the isolation interface and the center of rigidity of the isolation system, plus accidental eccentricity [ft (mm)] taken as 5% of the maximum building dimension perpendicular to the direction of force under consideration

E_{loop} = Energy dissipated, kip/in. (kN-mm), in an isolator unit during a full cycle of reversible load over a test displacement range from Δ^+ to Δ^-, as measured by the area enclosed by the loop of the force-deflection curve

F^+ = Maximum positive force, kips (kN) in an isolator unit during a single cycle of prototype testing at a displacement amplitude of Δ^+

F^- = Minimum negative force, kips (kN) in an isolator unit during a single cycle of prototype testing at a displacement amplitude of Δ^-

F_x = Lateral seismic force, kips (kN) at level x, as prescribed by Equation (17.5-9)

@seismicisolation
@seismicisolation

Table 17.5-1. Damping Factor, B_M.

Effective Damping, β_M (percentage of critical)[a,b]	B_M Factor
≤2	0.8
5	1.0
10	1.2
20	1.5
30	1.7
40	1.9
≥50	2.0

[a] The damping factor shall be based on the effective damping of the isolation system, determined in accordance with the requirements of Section 17.2.8.6.

[b] The damping factor shall be based on linear interpolation for effective damping values other than those given.

h_i, h_l, h_x = Height [ft (m)] above the isolation interface of level i, l, or x

h_{sx} = Height of story below level x

k_{eff} = Effective stiffness [kip/in (kN/mm)] of an isolator unit, as prescribed by Equation (17.8-1)

k_M = Effective stiffness [kip/in. (kN/mm)] of the isolation system in the horizontal direction under consideration

L = Effect of live load in Chapter 17

N = Number of isolator units

P_T = Ratio of the effective translational period of the isolation system to the effective torsional period of the isolation system, as calculated by dynamic analysis or as prescribed by Equation (17.5-4) but need not be taken as less than 1.0

r_I = Radius of gyration of the isolation system [ft (mm)]

R_I = Numerical coefficient related to the type of seismic force-resisting system above the isolation system

T_{fb} = Fundamental period of the structure above the isolation interface, determined using a modal analysis assuming fixed-base conditions, s

T_M = Effective period of the seismically isolated structure at the displacement D_M in the direction under consideration, as prescribed by Equation (17.5-2), s

V_b = Total lateral seismic design force or shear on elements of the isolation system or elements below the isolation system [kips (kN)], as prescribed by Equation (17.5-5)

V_s = Total lateral seismic design force or shear on elements above the base level [kips (kN)], as prescribed by Equation (17.5-6) and the limits of Section 17.5.4.3

V_{st} = Total unreduced lateral seismic design force or shear on elements above the base level [kips (kN)], as prescribed by Equation (17.5-7)

$\overline{V}_s$ = Sheer wave velocity

w_i, w_l, w_x = Portion of W that is located at or assigned to level i, l, or x [kips (kN)]

W = Effective seismic weight [kips (kN)] of the structure above the isolation interface, as defined by Section 12.7.2

W_s = Effective seismic weight [kips (kN)] of the structure above the isolation interface, as defined by Section 12.7.2, excluding the effective seismic weight [kips (kN)] of the base level

x_i, y_i = Horizontal distances [ft (mm)] from the center of mass to the ith isolator unit in the two horizontal axes of the isolation system

y = Distance, ft (mm) between the center of rigidity of the isolation system and the element of interest measured perpendicular to the direction of seismic loading under consideration

β_{eff} = Effective damping of the isolation system, as prescribed by Equation (17.8-2)

β_M = Effective damping of the isolation system at the displacement D_M, as prescribed by Equation (17.2-4)

Δ^+ = Maximum positive displacement, in. (mm) of an isolator unit during each cycle of prototype testing

Δ^- = Minimum negative displacement, in. (mm) of an isolator unit during each cycle of prototype testing

$\lambda_{(\text{ae,max})}$ = Property modification factor for calculation of the maximum value of the isolator property of interest, used to account for aging effects and environmental conditions, as defined in Section 17.2.8.4

$\lambda_{(\text{ae,min})}$ = Property modification factor for calculation of the minimum value of the isolator property of interest, used to account for aging effects and environmental conditions, as defined in Section 17.2.8.4

λ_{max} = Property modification factor for calculation of the maximum value of the isolator property of interest, used to account for all sources of isolator property variability, as defined in Section 17.2.8.4

λ_{min} = Property modification factor for calculation of the minimum value of the isolator property of interest, used to account for all sources of isolator property variability, as defined in Section 17.2.8.4

$\lambda_{(\text{spec,max})}$ = Property modification factor for calculation of the maximum value of the isolator property of interest, used to account for permissible manufacturing variation on the average properties of a group of same-sized isolators, as defined in Section 17.2.8.4

$\lambda_{(\text{spec,min})}$ = Property modification factor for calculation of the minimum value of the isolator property of interest, used to account for permissible manufacturing variation on the average properties of a group of same-sized isolators, as defined in Section 17.2.8.4

$\lambda_{(\text{test,max})}$ = Property modification factor for calculation of the maximum value of the isolator property of interest, used to account for heating, rate of loading, and scragging, as defined in Section 17.2.8.4

$\lambda_{(\text{test,min})}$ = Property modification factor for calculation of the minimum value of the isolator property of interest, used to account for heating, rate of loading, and scragging, as defined in Section 17.2.8.4

ΣE_M = Total energy dissipated [kip/in. (kN-mm)] in the isolation system during a full cycle of response at displacement D_M

$\Sigma|F_D^+|_{\text{max}}$ = Sum, for all isolator units, of the maximum absolute value of force [kips (kN)], at a positive displacement equal to D_M

$\Sigma|F_D^-|_{\text{max}}$ = Sum, for all isolator units, of the maximum absolute value of force [kips (kN)], at a negative displacement equal to D_M

17.2 GENERAL DESIGN REQUIREMENTS

17.2.1 Importance Factor All portions of the structure, including the structure above the isolation system, shall be assigned a risk category in accordance with Table 1.5-1. The Importance Factor, I_e, shall be taken as 1.0 for a seismically isolated structure, regardless of its risk category assignment.

@seismicisolation

17.2.2 Configuration Each isolated structure shall be designated as having a structural irregularity if the structural configuration above the isolation system has a Type 1 horizontal structural irregularity with a *TIR* greater than 1.4 or Type 1a, 1b, 4a, 4b vertical irregularity, as defined in Table 12.3-2.

17.2.3 Redundancy A redundancy factor, ρ, shall be assigned to the structure above the isolation system based on requirements of Section 12.3.4. The value of the redundancy factor, ρ, is permitted to be equal to 1.0 for isolated structures that do not have a structural irregularity, as defined in Section 17.2.2.

17.2.4 Isolation System

17.2.4.1 Environmental Conditions In addition to the requirements for vertical and lateral loads induced by wind and earthquake, the isolation system shall provide for other environmental conditions, including aging effects, creep, fatigue, operating temperature, and exposure to moisture or damaging substances.

17.2.4.2 Wind Forces Isolated structures shall resist design wind loads at all levels above the isolation interface. At the isolation interface, a wind-restraint system shall be provided to limit lateral displacement in the isolation system to a value equal to that required between floors of the structure above the isolation interface, in accordance with Section 17.5.6.

17.2.4.3 Fire Resistance Fire resistance for the isolation system shall provide at least the same degree of protection as the fire resistance required for the columns, walls, or other such gravity-bearing elements in the same region of the structure.

17.2.4.4 Lateral Restoring Force The isolation system shall be configured, for both upper bound and lower bound isolation system properties, to produce a restoring force such that the lateral force at the corresponding maximum displacement is at least 0.025 W greater than the lateral force at 50% of the corresponding maximum displacement.

17.2.4.5 Displacement Restraint The isolation system shall not be configured to include a displacement restraint that limits lateral displacement caused by risk-targeted maximum considered earthquake (MCE_R) ground motions to less than the total maximum displacement, D_{TM}, unless the seismically isolated structure is designed in accordance with all of the following criteria:

1. MCE_R response is calculated in accordance with the dynamic analysis requirements of Section 17.6, explicitly considering the nonlinear characteristics of the isolation system and the structure above the isolation system.
2. The ultimate capacity of the isolation system and structural elements below the isolation system shall exceed the strength and displacement demands of the MCE_R response.
3. The structure above the isolation system is checked for stability and ductility demand of the MCE_R response.
4. The displacement restraint does not become effective at a displacement less than 0.6 times the total maximum displacement.

17.2.4.6 Vertical-Load Stability Each element of the isolation system shall be designed to be stable under the design vertical load where it is subjected to a horizontal displacement equal to the total maximum displacement. The design vertical load shall be computed using load combination 2 of Section 17.2.7.1 for the maximum vertical load and load combination 3 of Section 17.2.7.1 for the minimum vertical load.

17.2.4.7 Overturning The factor of safety against global structural overturning at the isolation interface shall not be less than 1.0 for required load combinations. All gravity and seismic loading conditions shall be investigated. Seismic forces for overturning calculations shall be based on MCE_R ground motions, and W shall be used for the vertical restoring force.

Local uplift of individual elements shall not be allowed unless the resulting deflections do not cause overstress or instability of the isolator units or other structure elements.

17.2.4.8 Inspection and Replacement All the following items shall be addressed as part of the long-term inspection and replacement program:

1. Access for inspection and replacement of all components of the isolation system shall be provided.
2. Registered design professional (RDP) shall complete a final series of observations of structure separation areas and components that cross the isolation interface before the issuance of the certificate of occupancy for the seismically isolated structure. Such observations shall verify that conditions allow free and unhindered displacement of the structure up to the total maximum displacement and that components that cross the isolation interface have been constructed to accommodate the total maximum displacement.
3. Seismically isolated structures shall have a monitoring, inspection, and maintenance plan for the isolation system established by the RDP responsible for the design of the isolation system.
4. Remodeling, repair, or retrofitting at the isolation system interface, including that of components that cross the isolation interface, shall be performed under the direction of a RDP.

17.2.4.9 Quality Control A quality control testing program for isolator units shall be established by the RDP responsible for the structural design, incorporating the production testing requirements of Section 17.8.5.

17.2.5 Structural System

17.2.5.1 Horizontal Distribution of Force A horizontal diaphragm or other structural elements shall provide continuity above the isolation interface and shall have adequate strength and ductility to transmit forces from one part of the structure to another.

17.2.5.2 Minimum Building Separations Minimum separations between the isolated structure and surrounding retaining walls or other fixed obstructions shall not be less than the total maximum displacement.

17.2.5.3 Nonbuilding Structures Nonbuilding structures shall be designed and constructed in accordance with the requirements of Chapter 15 using design displacements and forces, calculated in accordance with Sections 17.5 or 17.6.

17.2.5.4 Steel Ordinary Concentrically Braced Frames Steel ordinary concentrically braced frames are permitted as the seismic force-resisting system in seismically isolated structures assigned to Seismic Design Categories D, E, and F and are permitted to a height of 160 ft (48.4 m) or less, provided all the following design requirements are satisfied:

1. The value of R_I, as defined in Section 17.5.4 is 1.0.
2. The total maximum displacement (D_{TM}), as defined in Equation (17.5-3), shall be increased by a factor of 1.2.

@seismicisolation

17.2.5.5 Isolation System Connections Moment-resisting connections of structural steel elements of the seismic isolation system below the base level are permitted to conform to the requirements for ordinary steel moment frames of AISC 341, E1.6a and E1.6b.

17.2.6 Elements of Structures and Nonstructural Components Parts or portions of an isolated structure, permanent nonstructural components and the attachments to them, and the attachments for permanent equipment supported by a structure shall be designed to resist seismic forces and displacements, as prescribed by this section and the applicable requirements of Chapter 13.

17.2.6.1 Components at or above the Isolation Interface Elements of seismically isolated structures and nonstructural components, or portions thereof, which are at or above the isolation interface, shall be designed to resist a total lateral seismic force equal to the maximum dynamic response of the element or component under consideration, determined using a response history analysis.

EXCEPTION: Elements of seismically isolated structures and nonstructural components or portions designed to resist seismic forces and displacements, as prescribed in Chapter 12 or 13 as appropriate, are not required to meet this provision.

17.2.6.2 Components Crossing the Isolation Interface Elements of seismically isolated structures and nonstructural components, or portions thereof, which cross the isolation interface, shall be designed to withstand the total maximum displacement and to accommodate, on a long-term basis, any permanent residual displacement.

17.2.6.3 Components below the Isolation Interface Elements of seismically isolated structures and nonstructural components, or portions thereof, which are below the isolation interface, shall be designed and constructed in accordance with the requirements of Section 12.1 and Chapter 13.

17.2.7 Seismic Load Effects and Load Combinations All members of the isolated structure, including those that are not part of the seismic force-resisting system, shall be designed using the seismic load effects of Section 12.4, and the additional load combinations of Section 17.2.7.1, for the design of the isolation system and for the testing of prototype isolator units.

17.2.7.1 Isolator Unit Vertical Load Combinations The average, minimum, and maximum vertical load on each isolator unit type shall be computed from application of horizontal seismic forces, Q_E, caused by MCE_R ground motions and the following applicable vertical load combinations:

1. Average vertical load: load corresponding to 1.0 dead load plus 0.5 live load.
2. Maximum vertical load: load combination 6 of Section 2.3.6, where E is given by Equation (12.4-1) and $0.2S_{DS}$ is replaced by $0.12S_{MS}$ in Equation (12.4-4a).
3. Minimum vertical load: load combination 7 of Section 2.3.6, where E is given by Equation (12.4-2) and $0.2S_{DS}$ is replaced by $0.12S_{MS}$ in Equation (12.4-4a).

17.2.8 Isolation System Properties

17.2.8.1 Isolation System Component Types All components of the isolation system shall be categorized and grouped in terms of common type and size of isolator unit and common type and size of supplementary damping device, if such devices are also components of the isolation system.

17.2.8.2 Isolator Unit Nominal Properties Isolator unit nominal design properties shall be based on average properties over the three cycles of prototype testing, specified by Item 2 of Section 17.8.2.2. Variation in isolator unit properties with vertical load are permitted to be established based on a single representative deformation cycle, by averaging the properties determined using the three vertical load combinations specified in Section 17.2.7.1, at each displacement level, where required to be considered by Section 17.8.2.2.

EXCEPTION: If the measured values of isolator unit effective stiffness and effective damping for load combination 1 of Section 17.2.7.1 differ by less than 15% from those based on the average of measured values for the three vertical load combinations of Section 17.2.7.1, then nominal design properties are permitted to be computed only for load combination 1 of Section 17.2.7.1.

17.2.8.3 Bounding Properties of Isolation System Components Bounding properties of isolation system components shall be developed for each isolation system component type. Bounding properties shall include variation in all of the following component properties:

1. Measured by prototype testing, Item 2 of Section 17.8.2.2, considering variation in prototype isolator unit properties caused by required variation in vertical test load, rate of test loading or velocity effects, effects of heating during cyclic motion, history of loading, scragging (temporary degradation of mechanical properties with repeated cycling), and other potential sources of variation measured by prototype testing;
2. Permitted by manufacturing specification tolerances used to determine acceptability of production isolator units, as required by Section 17.8.5; and
3. Because of aging and environmental effects, including creep, fatigue, contamination, operating temperature and duration of exposure to that temperature and wear over the life of the structure.

17.2.8.4 Property Modification Factors Maximum and minimum property modification (λ) factors shall be used to account for the variation of the nominal design parameters of each isolator unit type for the effects of heating caused by cyclic dynamic motion, loading rate, scragging and recovery, variability in production bearing properties, temperature, aging, environmental exposure, and contamination. When manufacturer-specific qualification test data, in accordance with Section 17.8, have been approved by the RDP these data are permitted to be used to develop the property modification factors, and the maximum and minimum limits of Equations (17.2-1) and (17.2-2) need not apply. When qualification test data, in accordance with Section 17.8, have not been approved by the RDP the maximum and minimum limits of Equations (17.2-1) and (17.2-2) shall apply.

Property modification factors (λ) shall be developed for each isolator unit type, and when applied to the nominal design parameters shall envelop the hysteretic response for the range of demands from $\pm 0.5D_M$ up to and including the maximum displacement, $\pm D_M$. Property modification factors for environmental conditions are permitted to be developed from data that need not satisfy the similarity requirements of Section 17.8.2.7.

@seismicisolation
@seismicisolation

For each isolator unit type, the maximum property modification factor, λ_{max}, and the minimum property modification factor, λ_{min}, shall be established from contributing property modification factors in accordance with Equations (17.2-1) and (17.2-2), respectively:

$$\lambda_{max} = (1 + (0.75 \times (\lambda_{(ae,max)} - 1))) \times \lambda_{(test,max)} \times \lambda_{(spec,max)} \geq 1.8 \quad (17.2\text{-}1)$$

$$\lambda_{min} = (1 - (0.75 \times (1 - \lambda_{(ae,min)}))) \times \lambda_{(test,min)} \times \lambda_{(spec,min)} \leq 0.60 \quad (17.2\text{-}2)$$

where

$\lambda_{(ae,max)}$ = Property modification factor for calculation of the maximum value of the isolator property of interest, used to account for aging effects and environmental conditions;

$\lambda_{(ae,min)}$ = Property modification factor for calculation of the minimum value of the isolator property of interest, used to account for aging effects and environmental conditions;

$\lambda_{(test,max)}$ = Property modification factor for calculation of the maximum value of the isolator property of interest, used to account for heating, rate of loading, and scragging;

$\lambda_{(test,min)}$ = Property modification factor for calculation of the minimum value of the isolator property of interest, used to account for heating, rate of loading, and scragging;

$\lambda_{(spec,max)}$ = Property modification factor for calculation of the maximum value of the isolator property of interest, used to account for permissible manufacturing variation on the average properties of a group of same-sized isolators; and

$\lambda_{(spec,min)}$ = Property modification factor for calculation of the minimum value of the isolator property of interest, used to account for permissible manufacturing variation on the average properties of a group of same-sized isolators.

EXCEPTION: If the prototype isolator testing is conducted on a full-scale specimen that satisfies the dynamic test data of Section 17.8.2.3, then the values of the property modification factors shall be based on the test data, and the upper and lower limits of Equations (17.2-1) and (17.2-2) need not apply.

17.2.8.5 Upper Bound and Lower Bound Force-Deflection Behavior of Isolation System Components A mathematical model of upper bound force-deflection (loop) behavior of each type of isolation system component shall be developed. Upper bound force-deflection behavior of isolation system components that are essentially hysteretic devices (e.g., isolator units) shall be modeled using the maximum values of isolator properties calculated using the property modification factors of Section 17.2.8.4. Upper bound force-deflection behavior of isolation system components that are essentially viscous devices (e.g., supplementary viscous dampers) shall be modeled in accordance with the requirements of Chapter 18 for such devices.

A mathematical model of lower bound force-deflection (loop) behavior of each type of isolation system component shall be developed. Lower bound force-deflection behavior of isolation system components that are essentially hysteretic devices (e.g., isolator units) shall be modeled using the minimum values of isolator properties calculated using the property modification factors of Section 17.2.8.4. Lower bound force-deflection behavior of isolation system components that are essentially viscous devices (e.g., supplementary viscous dampers) shall be modeled in accordance with the requirements of Chapter 18 for such devices.

17.2.8.6 Isolation System Properties at Maximum Displacements The effective stiffness, k_M, of the isolation system at the maximum displacement, D_M, shall be computed using both upper bound and lower bound force-deflection behavior of individual isolator units, in accordance with Equation (17.2-3):

$$k_M = \frac{\sum |F_M^+| + \sum |F_M^-|}{2D_M} \quad (17.2\text{-}3)$$

The effective damping, β_M, of the isolation system at the maximum displacement, D_M [in. (mm)], shall be computed using both upper bound and lower bound force-deflection behavior of individual isolator units, in accordance with Equation (17.2-4):

$$\beta_M = \frac{\sum E_M}{2\pi k_M D_M^2} \quad (17.2\text{-}4)$$

where

$\sum E_M$ = Total energy dissipated in the isolation system during a full cycle of response at the displacement D_M, kips-in. (kN-mm);

$\sum F_M^+$ = Sum, for all isolator units, of the absolute value of force at a positive displacement equal to D_M, kips (kN); and;

$\sum F_M^-$ = Sum, for all isolator units, of the absolute value of force at a negative displacement equal to D_M, kips (kN).

17.2.8.7 Upper Bound and Lower Bound Isolation System Properties at Maximum Displacement The analysis of the isolation system and structure shall be performed separately for upper bound and lower bound properties, and the governing case for each response parameter of interest shall be used for design. In addition, the analysis shall comply with all of the following:

1. For the equivalent lateral force procedure, and for the purposes of establishing minimum forces and displacements for dynamic analysis, the following variables shall be calculated independently for upper bound and lower bound isolation system properties: k_M and β_M per Section 17.2.8.6 [Equations (17.2-3) and (17.2-4)], D_M per Section 17.5.3.1 [Equation (17.5-1)], T_M per Section 17.5.3.2 [Equation (17.5-2)], D_{TM} per Section 17.5.3.3 [Equation (17.5-3)], V_b per Section 17.5.4.1 [Equation (17.5-5)], and V_s and V_{st} per Section 17.5.4.2 [Equations (17.5-6) and (17.5-7)];
2. Limitations on V_s established in Section 17.5.4.3 shall be evaluated independently for both upper bound and lower bound isolation system properties, and the most adverse requirement shall govern.
3. For the equivalent lateral force procedure and for the purposes of establishing minimum story shear forces for response spectrum analysis, the vertical force distribution from Section 17.5.5 shall be determined separately for upper bound and lower bound isolation system properties. This determination will require independent calculation of F_1, F_x, C_{vx}, and k, per Equations (17.5-8) through (17.5-11), respectively.

@seismicisolation
@seismicisolation

17.3 SEISMIC HAZARD

17.3.1 Spectral Response Acceleration Parameters and Response Spectrum The MCE_R spectral response acceleration parameters (S_{MS} and S_{M1}) and the MCE_R spectrum shall be determined in accordance with Section 11.4.

17.3.2 Ground Motions for Response History Analysis Where response history analysis in accordance with Section 17.6.3.4 is used to design seismically isolated structures, the provisions of Section 16.2 shall apply except that in lieu of the requirements of Section 16.2.3.1, the period range shall be determined in accordance with the following:

A period range shall be determined corresponding to the vibration periods that significantly contribute to the structure's lateral dynamic response. The upper bound of this period range shall be greater than or equal to $1.25T_M$, as determined using lower bound isolation system properties. The lower bound period of this period range shall be established such that the period range includes at least the number of modes necessary to achieve 90% mass participation in each principal horizontal direction and shall not exceed T_{fb}. Where vertical response is considered in the analysis, the lower bound period of the period range used for the modification of vertical components of ground motion need not be taken as less than the larger of 0.1 s or the lowest period at which significant vertical mass participation occurs.

17.4 ANALYSIS PROCEDURE SELECTION

Seismically isolated structures, except those defined in Section 17.4.1, shall be designed using the dynamic procedures of Section 17.6. Where supplementary viscous dampers are used, the response history analysis procedures of Section 17.4.2.2 shall be used.

17.4.1 Equivalent Lateral Force Procedure The equivalent lateral force procedure of Section 17.5 is permitted to be used for design of a seismically isolated structure provided that all of the following items are satisfied. These requirements shall be evaluated separately for upper bound and lower bound isolation system properties, and the more restrictive requirement shall govern.

1. The structure is located on a Site Class A, B, C, or D site.
2. The effective period of the isolated structure at the maximum displacement, D_M, is less than or equal to 5.0 s.
3. The structure above the isolation interface is less than or equal to four stories or 65 ft (19.8 m) in structural height measured from the base level.

   EXCEPTION: These limits are permitted to be exceeded if there is no tension or uplift on the isolators.
4. The effective damping of the isolation system at the maximum displacement, D_M, is less than or equal to 30%.
5. The effective period of the isolated structure, T_M, is greater than three times the elastic, fixed-base period of the structure above the isolation system, determined using a rational modal analysis.
6. The structure above the isolation system does not have a structural irregularity, as defined in Section 17.2.2.
7. The isolation system meets all of the following criteria:
   (a) The effective stiffness of the isolation system at the maximum displacement is greater than one-third of the effective stiffness at 20% of the maximum displacement.
   (b) The isolation system is capable of producing a restoring force, as specified in Section 17.2.4.4.
   (c) The isolation system does not limit maximum earthquake displacement to less than the total maximum displacement, D_{TM}.

17.4.2 Dynamic Procedures The dynamic procedures of Section 17.6 are permitted to be used as specified in this section.

17.4.2.1 Response Spectrum Analysis Procedure Response spectrum analysis procedure shall not be used for design of a seismically isolated structure unless the structure, site, and isolation system meet the criteria of Section 17.4.1, Items 1, 2, 3, 4, and 6.

17.4.2.2 Response History Analysis Procedure The response history analysis procedure is permitted to be used for design of any seismically isolated structure and shall be used for design of all seismically isolated structures not meeting the criteria of Section 17.4.2.1.

17.5 EQUIVALENT LATERAL FORCE PROCEDURE

17.5.1 General Where the equivalent lateral force procedure is used to design seismically isolated structures, the requirements of this section shall apply.

17.5.2 Deformation Characteristics of the Isolation System Minimum lateral earthquake design displacements and forces on seismically isolated structures shall be based on the deformation characteristics of the isolation system. The deformation characteristics of the isolation system include the effects of the wind-restraint system if such a system is used to meet the design requirements of this standard. The deformation characteristics of the isolation system shall be based on properly substantiated prototype tests performed in accordance with Section 17.8 and shall incorporate property modification factors in accordance with Section 17.2.8.4.

The analysis of the isolation system and structure shall be performed separately for upper bound and lower bound properties, and the governing case for each response parameter of interest shall be used for design.

17.5.3 Minimum Lateral Displacements Required for Design

17.5.3.1 Maximum Displacement The isolation system shall be designed and constructed to withstand, at a minimum, the maximum displacement, D_M, determined using upper bound and lower bound properties, in the most critical direction of horizontal response, calculated using Equation (17.5-1):

$$D_M = \frac{gS_{M1}T_M}{4\pi^2 B_M} \tag{17.5-1}$$

where

g = Acceleration caused by gravity [in./s^2 (mm/s^2)] if the units of the displacement D_M are in in. (mm);
S_{M1} = MCE_R 5% damped spectral acceleration parameter at 1 s period in units of g-sec, as determined in Section 11.4.4 or 11.4.8;
T_M = Effective period of the seismically isolated structure (s) at the displacement D_M in the direction under consideration, as prescribed by Equation (17.5-2); and
B_M = Numerical coefficient as set forth in Table 17.5-1 for the effective damping of the isolation system β_M at the displacement D_M.

17.5.3.2 Effective Period at the Maximum Displacement The effective period of the isolated structure, T_M, at the maximum

@seismicisolation

displacement, D_M, shall be determined using upper bound and lower bound deformational characteristics of the isolation system and Equation (17.5-2):

$$T_M = 2\pi\sqrt{\frac{W}{k_M g}} \tag{17.5-2}$$

where

W = Effective seismic weight of the structure above the isolation interface as defined in Section 12.7.2;
k_M = Effective stiffness [kip/in. (kN/mm)] of the isolation system at the maximum displacement, D_M, as prescribed by Equation (17.2-3); and
g = Acceleration caused by gravity [in./s^2 (mm/s^2)] if the units of k_M are in kip/in. (kN/mm).

17.5.3.3 Total Maximum Displacement The total maximum displacement, D_{TM}, of elements of the isolation system shall include additional displacement caused by actual and accidental torsion, calculated from the spatial distribution of the lateral stiffness of the isolation system and the most disadvantageous location of eccentric mass. The total maximum displacement, D_{TM}, of elements of an isolation system shall not be taken as less than that prescribed by Equation (17.5-3):

$$D_{TM} = D_M\left[1 + \left(\frac{y}{P_T^2}\right)\frac{12e}{b^2 + d^2}\right] \tag{17.5-3}$$

where

D_M = Displacement at the center of rigidity of the isolation system in the direction under consideration, as prescribed by Equation (17.5-1);
y = Distance [in. (mm)] between the centers of rigidity of the isolation system and the element of interest measured perpendicular to the direction of seismic loading under consideration;
e = Actual eccentricity measured in plan between the center of mass of the structure above the isolation interface and the center of rigidity of the isolation system, plus accidental eccentricity [ft (mm)], taken as 5% of the longest plan dimension of the structure perpendicular to the direction of force under consideration;
b = Shortest plan dimension of the structure [ft (mm)] measured perpendicular to d;
d = Longest plan dimension of the structure [ft (mm)]; and
P_T = Ratio of the effective translational period of the isolation system to the effective torsional period of the isolation system, as calculated by dynamic analysis, or as prescribed by Equation (17.5-4) but need not be taken as less than 1.0.

$$P_{\mathrm{T}} = \frac{1}{r_I}\sqrt{\frac{\sum_N^{i=1}(x_i^2 + y_i^2)}{N}} \tag{17.5-4}$$

where

x_i, y_i = Horizontal distances [ft (mm)] from the center of mass to the ith isolator unit in the two horizontal axes of the isolation system;
N = Number of isolator units; and
r_I = Radius of gyration of the isolation system [ft (mm)], which is equal to $[(b^2 + d^2)/12]^{1/2}$ for isolation systems of rectangular plan dimension, $b \times d$.

The total maximum displacement, D_{TM}, shall not be taken as less than 1.15 times D_M.

17.5.4 Minimum Lateral Forces Required for Design

17.5.4.1 Isolation System and Structural Elements below the Base Level The isolation system, the foundation, and all structural elements below the base level shall be designed and constructed to withstand a minimum lateral seismic force, V_b, using all of the applicable requirements for a nonisolated structure, as prescribed by the value of Equation (17.5-5), determined using both upper bound and lower bound isolation system properties:

$$V_b = k_M D_M \tag{17.5-5}$$

where k_M is the effective stiffness [kip/in. (kN/mm)] of the isolation system at the displacement D_M, as prescribed by Equation (17.2-3), and D_M is the maximum displacement [in. (mm)] at the center of rigidity of the isolation system in the direction under consideration, as prescribed by Equation (17.5-1).

V_b shall not be taken as less than the maximum force in the isolation system at any displacement up to and including the maximum displacement, D_M, as defined in Section 17.5.3

Overturning loads on elements of the isolation system, the foundation, and structural elements below the base level caused by lateral seismic force, V_b, shall be based on the vertical distribution of force of Section 17.5.5, except that the unreduced lateral seismic design force, V_{st}, shall be used in lieu of V_s in Equation (17.5-9).

17.5.4.2 Structural Elements above the Base Level The structure above the base level shall be designed and constructed using all of the applicable requirements for a nonisolated structure for a minimum shear force, V_s, determined using upper bound and lower bound isolation system properties, as prescribed by Equation (17.5-6):

$$V_s = \frac{V_{st}}{R_I} \tag{17.5-6}$$

where R_I is the numerical coefficient related to the type of seismic force-resisting system above the isolation system, and V_{st} is the total unreduced lateral seismic design force or shear on elements above the base level, as prescribed by Equation (17.5-7).

The R_I factor shall be based on the type of seismic force-resisting system used for the structure above the base level in the direction of interest and shall be three-eighths of the value of R given in Table 12.2-1, with a maximum value not greater than 2.0 and a minimum value not less than 1.0.

EXCEPTION: The value of R_i is permitted to be taken as greater than 2.0, provided the strength of the structure above the base level in the direction of interest, as determined by nonlinear static analysis at a roof displacement corresponding to a maximum story drift the lesser of the MCE$_{\mathrm{R}}$ drift or $0.015h_{sx}$, is not less than 1.1 times V_b.

The total unreduced lateral seismic force or shear on elements above the base level shall be determined using upper bound and lower bound isolation system properties, as prescribed by Equation (17.5-7):

@seismicisolation

$$V_{st} = V_b \left(\frac{W_s}{W}\right)^{(1-2.5\beta m)} \quad (17.5\text{-}7)$$

where W is the effective seismic weight [kips (kN)] of the structure above the isolation interface, as defined in Section 12.7.2; and W_s is the effective seismic weight [kips (kN)] of the structure above the isolation interface, as defined in Section 12.7.2, excluding the effective seismic weight [kips (kN)] of the base level.

The effective seismic weight W_s in Equation (17.5-7) shall be taken as equal to W when the average distance from the top of the isolator to the underside of the base level floor framing above the isolators exceeds 3 ft (0.9 m).

EXCEPTION: For isolation systems whose hysteretic behavior is characterized by an abrupt transition from preyield to postyield or preslip to postslip behavior, the exponent term $(1 - 2.5\beta_M)$ in Equation (17.5-7) shall be replaced by $(1 - 3.5\beta_M)$.

17.5.4.3 Limits on V_s The value of V_s shall not be taken as less than each of the following:

1. The lateral seismic force required by Section 12.8 for a fixed-base structure of the same effective seismic weight, W_s, and a period equal to the period of the isolation system using the upper bound properties, T_M;
2. The base shear corresponding to the factored design wind load; and
3. The lateral seismic force, V_{st}, calculated using Equation (17.5-7), and with V_b set equal to the force required to fully activate the isolation system using the greater of the upper bound properties, or
   (a) 1.5 times the nominal properties for the yield level of a softening system,
   (b) The ultimate capacity of a sacrificial wind-restraint system,
   (c) The breakaway friction force of a sliding system, or
   (d) The force at zero displacement of a sliding system following a complete dynamic cycle of motion at D_M.

17.5.5 Vertical Distribution of Force The lateral seismic force, V_s, shall be distributed over the height of the structure above the base level, using upper bound and lower bound isolation system properties, using the following equations:

$$F_1 = \frac{(V_b - V_{st})}{R_I} \quad (17.5\text{-}8)$$

and

$$F_x = C_{vx} V_s \quad (17.5\text{-}9)$$

and

$$C_{vx} = \frac{w_x h_x^k}{\sum_{i=2}^{n} w_i h_i^k} \quad (17.5\text{-}10)$$

and

$$k = 14\beta_M T_{fb} \quad (17.5\text{-}11)$$

where

F_1 = Lateral seismic force [kips (kN)] induced at level 1, the base level;
F_x = Lateral seismic force [kips (kN)] induced at level x, $x > 1$;
C_{vx} = Vertical distribution factor;
V_s = Total lateral seismic design force or shear on elements above the base level, as prescribed by Equation (17.5-6) and the limits of Section 17.5.4.3;
$w_i w_x$ = Portion of W_s that is located at or assigned to level i or x;
$h_i h_x$ = Height above the isolation interface of level i or x; and
T_{fb} = Fundamental period, in s, of the structure above the isolation interface determined using a rational modal analysis assuming fixed-base conditions.

EXCEPTION: In lieu of Equations (17.5-6) and (17.5-9), the lateral seismic force F_x is permitted to be calculated as the average value of the force at level x in the direction of interest, using the results of a simplified stick model of the building and a lumped representation of the isolation system using response history analysis scaled to V_b/R_I at the base level.

17.5.6 Drift Limits The maximum story drift of the structure above the isolation system shall not exceed $0.015h_{sx}$. The drift shall be calculated by Equation (12.8-15) with C_d for the isolated structure equal to R_I, as defined in Section 17.5.4.2.

17.6 DYNAMIC ANALYSIS PROCEDURES

17.6.1 General Where dynamic analysis is used to design seismically isolated structures, the requirements of this section shall apply.

17.6.2 Modeling The mathematical models of the isolated structure, including the isolation system, the seismic force-resisting system, and other structural elements, shall conform to Section 12.7.3 and to the requirements of Sections 17.6.2.1 and 17.6.2.2.

17.6.2.1 Isolation System The isolation system shall be modeled using deformational characteristics developed in accordance with Section 17.2.8. The lateral displacements and forces shall be computed separately for upper bound and lower bound isolation system properties, as defined in Section 17.2.8.5. The isolation system shall be modeled with sufficient detail to capture all of the following:

1. Spatial distribution of isolator units;
2. Translation, in both horizontal directions, and torsion of the structure above the isolation interface considering the most disadvantageous location of eccentric mass;
3. Overturning and uplift forces on individual isolator units; and
4. Effects of vertical load, bilateral load, and/or the rate of loading if the force-deflection properties of the isolation system are dependent on one or more of these attributes.

The total maximum displacement, D_{TM}, across the isolation system shall be calculated using a model of the isolated structure that incorporates the force-deflection characteristics of nonlinear elements of the isolation system and the seismic force-resisting system.

17.6.2.2 Isolated Structure The maximum displacement of each floor and design forces and displacements in elements of the seismic force-resisting system are permitted to be calculated using a linear elastic model of the isolated structure, provided that all elements of the seismic force-resisting system of the structure above the isolation system remain essentially elastic.

Seismic force-resisting systems with essentially elastic elements include, but are not limited to, regular structural systems designed for a lateral force not less than 100% of V_s determined in accordance with Sections 17.5.4.2 and 17.5.4.3.

@seismicisolation

The analysis of the isolation system and structure shall be performed separately for upper bound and lower bound properties, and the governing case for each response parameter of interest shall be used for design.

17.6.3 Description of Procedures

17.6.3.1 General Response spectrum analysis shall be performed in accordance with Section 12.9 and the requirements of Section 17.6.3.3. Response history analysis shall be performed in accordance with the requirements of Section 17.6.3.4.

17.6.3.2 MCE_R Ground Motions The MCE_R ground motions of Section 17.3 shall be used to calculate the lateral forces and displacements in the isolated structure, the total maximum displacement of the isolation system, and the forces in the isolator units, isolator unit connections, and supporting framing immediately above and below the isolators used to resist isolator P-delta demands.

17.6.3.3 Response Spectrum Analysis Procedure Response spectrum analysis shall be performed using a modal damping value for the fundamental mode in the direction of interest not greater than the effective damping of the isolation system or 30% of critical, whichever is less. Modal damping values for higher modes shall be selected consistent with those that would be appropriate for response spectrum analysis of the structure above the isolation system assuming a fixed base.

Response spectrum analysis used to determine the total maximum displacement shall include simultaneous excitation of the model by 100% of the ground motion in the critical direction and 30% of the ground motion in the perpendicular, horizontal direction. The maximum displacement of the isolation system shall be calculated as the vector sum of the two orthogonal displacements.

17.6.3.4 Response History Analysis Procedure Response history analysis shall be performed for a set of ground motion pairs selected and scaled in accordance with Section 17.3.2. Each pair of ground motion components shall be applied simultaneously to the model, considering the most disadvantageous location of eccentric mass. The maximum displacement of the isolation system shall be calculated from the vector sum of the two orthogonal displacements at each time step.

The parameters of interest shall be calculated for each ground motion used for the response history analysis, and the average value of the response parameter of interest shall be used for design.

17.6.3.4.1 Accidental Mass Eccentricity Torsional response resulting from lack of symmetry in mass and stiffness shall be accounted for in the analysis. In addition, accidental eccentricity consisting of displacement of the center of mass from the computed location by an amount equal to 5% of the diaphragm dimension shall be considered separately in each of two orthogonal directions at the level under consideration.

The effects of accidental eccentricity are permitted to be accounted for by amplifying forces, drifts, and deformations determined from an analysis, using only the computed center of mass, provided that factors used to amplify forces, drifts, and deformations of the center-of-mass analysis are shown to produce results that bound all the mass-eccentric cases.

17.6.4 Minimum Lateral Displacements and Forces

17.6.4.1 Isolation System and Structural Elements below the Base Level The isolation system, foundation, and all structural elements below the base level shall be designed using all of the applicable requirements for a nonisolated structure and the forces obtained from the dynamic analysis without reduction, but the design lateral force shall not be taken as less than 90% of V_b determined by Equation (17.5-5).

The total maximum displacement of the isolation system shall not be taken as less than 80% of D_{TM}, as prescribed by Section 17.5.3.3, except that D'_M is permitted to be used in lieu of D_M where

$$D'_M = \frac{D_M}{\sqrt{1 + (T/T_M)^2}} \tag{17.6-1}$$

and

D_M = Maximum displacement [in. (mm)] at the center of rigidity of the isolation system in the direction under consideration, as prescribed by Equation (17.5-1);

T = Elastic, fixed-base period, in s, of the structure above the isolation system, as determined by Section 12.8.2, including the coefficient C_u, if the approximate period formulas are used to calculate the fundamental period; and

T_M = Effective period, in s, of the seismically isolated structure, at the displacement D_M in the direction under consideration, as prescribed by Equation (17.5-2).

17.6.4.2 Structural Elements above the Base Level Subject to the procedure-specific limits of this section, structural elements above the base level shall be designed using the applicable requirements for a nonisolated structure and the forces obtained from the dynamic analysis reduced by a factor of R_I, as determined in accordance with Section 17.5.4.2.

For response spectrum analysis, the design shear at any story shall not be less than the story shear resulting from application of the forces calculated using Equation (17.5-9) and a value of V_b equal to the base shear obtained from the response spectrum analysis in the direction of interest.

For response history analysis of regular structures, the value of V_b shall not be taken as less than 80% of that determined in accordance with Section 17.5.4.1, and the value V_s shall not be taken as less than 100% of the limits specified by Section 17.5.4.3.

For response history analysis of irregular structures, the value of V_b shall not be taken as less than 100% of that determined in accordance with Section 17.5.4.1, and the value V_s shall not be taken as less than 100% of the limits specified by Section 17.5.4.3.

17.6.4.3 Scaling of Results Where the factored lateral shear force on structural elements, determined using either the response spectrum or response history procedure, is less than the minimum values prescribed by Sections 17.6.4.1 and 17.6.4.2, all design parameters shall be adjusted upward proportionally.

17.6.4.4 Drift Limits Maximum story drift corresponding to the design lateral force, including displacement caused by vertical deformation of the isolation system, shall comply with either of the following limits:

1. Where response spectrum analysis is used, the maximum story drift of the structure above the isolation system shall not exceed $0.015h_{sx}$.
2. Where response history analysis based on the force-deflection characteristics of nonlinear elements of the seismic force-resisting system is used, the maximum story drift of the structure above the isolation system shall not exceed $0.020h_{sx}$.

@seismicisolation
@seismicisolation

Drift shall be calculated using Equation (12.8-15), with the C_d of the isolated structure equal to R_I as defined in Section 17.5.4.2.

The secondary effects of the maximum lateral displacement of the structure above the isolation system, combined with gravity forces, shall be investigated if the story drift ratio exceeds $0.010/R_I$.

17.7 DESIGN REVIEW

An independent design review of the isolation system and related test programs shall be performed by one or more individuals possessing knowledge of the following items, with a minimum of one reviewer being a registered design professional (RDP). Isolation system design review shall include, but not be limited to, all the following:

1. Project design criteria, including site-specific spectra and ground motion histories.
2. Preliminary design, including the selection of the devices, determination of the maximum displacement, the total maximum displacement, and the lateral force level.
3. Review of qualification data and appropriate property modification factors for the manufacturer and device selected.
4. Prototype testing program (Section 17.8.2).
5. Final design of the entire structural system and all supporting analyses, including modeling of isolators for response history analysis, if performed.
6. Isolator production testing program (Section 17.8.5).

17.8 TESTING

17.8.1 General The deformation characteristics and damping values of the isolation system used in the design and analysis of seismically isolated structures shall be based on tests of a selected sample of the components before construction, as described in this section. The isolation system components to be tested shall include the wind-restraint system if such a system is used in the design.

The tests specified in this section are for establishing and validating the isolator unit and isolation system test properties that are used to determine design properties of the isolation system, in accordance with Section 17.2.8.

17.8.1.1 Qualification Tests Isolation device manufacturers shall submit, for approval by the RDP the results of qualification tests, analysis of test data, and supporting scientific studies that are permitted to be used to quantify the effects of heating caused by cyclic dynamic motion, loading rate, scragging, variability and uncertainty in production bearing properties, temperature, aging, environmental exposure, and contamination. The qualification testing shall be applicable to the component types, models, materials, and sizes to be used in the construction. The qualification testing shall have been performed on components manufactured by the same manufacturer supplying the components to be used in the construction. When scaled specimens are used in the qualification testing, principles of scaling and similarity shall be used in the interpretation of the data.

17.8.2 Prototype Tests Prototype tests shall be performed separately on two full-size specimens (or sets of specimens, as appropriate) of each predominant type and size of isolator unit of the isolation system. The test specimens shall include the wind-restraint system if such a system is used in the design. Specimens tested shall not be used for construction unless they are accepted by the RDP responsible for the design of the structure.

17.8.2.1 Record For each cycle of each test, the force-deflection behavior of the test specimen shall be recorded.

17.8.2.2 Sequence and Cycles Each of the following sequence of tests shall be performed for the prescribed number of cycles, at a vertical load equal to the average dead load plus one-half the effects caused by live load on all isolator units of a common type and size. Before these tests, the production set of tests specified in Section 17.8.5 shall be performed on each isolator:

1. Twenty fully reversed cycles of loading at a lateral force corresponding to the wind design force.
2. The sequence of either Item (a) or Item (b) shall be performed:
   (a) Three fully reversed cycles of loading at each of the following increments of the displacement: $0.25D_M$, $0.5D_M$, $0.67D_M$, and $1.0D_M$, where D_M is determined in Section 17.5.3.1 or Section 17.6, as appropriate.
   (b) The following sequence, performed dynamically at the effective period, T_M: continuous loading of one fully reversed cycle at each of the increments of the maximum displacement, that is, $1.0D_M$, $0.67D_M$, $0.5D_M$, and $0.25D_M$ followed by continuous loading of one fully reversed cycle at $0.25D_M$, $0.5D_M$, $0.67D_M$, and $1.0D_M$. A rest interval is permitted between these two sequences.
3. Three fully reversed cycles of loading at the maximum displacement, $1.0D_M$.
4. The sequence of either Item (a) or Item (b) shall be performed:
   (a) $30S_{M1}/(S_{MS}B_M)$, but not fewer than 10, continuous fully reversed cycles of loading at 0.75 times the maximum displacement, $0.75D_M$.
   (b) The test of Item (a), performed dynamically at the effective period, T_M. This test may comprise separate sets of multiple cycles of loading, with each set consisting of not fewer than five continuous cycles.

If an isolator unit is also a vertical load-carrying element, then Item 3 of the sequence of cyclic tests specified previously shall be performed for two additional vertical load cases specified in Section 17.2.7.1. The load increment caused by earthquake overturning, Q_E, shall be equal to or greater than the peak earthquake vertical force response corresponding to the test displacement being evaluated. In these tests, the combined vertical load shall be taken as the typical or average downward force on all isolator units of a common type and size. Axial load and displacement values for each test shall be the greater of those determined by analysis using upper bound and lower bound values of isolation system properties, determined in accordance with Section 17.2.8.5. The effective period T_M shall be the lower of those determined by analysis using upper bound and lower bound values.

17.8.2.3 Dynamic Testing Tests specified in Section 17.8.2.2 shall be performed dynamically at the lower of the effective periods, T_M, determined using upper bound and lower bound properties.

Dynamic testing shall not be required if the prototype testing has been performed dynamically on similar-sized isolators that meet the requirements of Section 17.8.2.7, and the testing was conducted at similar loads and accounted for the effects of velocity, amplitude of displacement, and heating effects. The prior dynamic prototype test data shall be used to establish factors that adjust three-cycle average values of k_d and E_{loop} to account for the difference in test velocity and heating effects and to establish $\lambda_{(test,min)}$ and $\lambda_{(test,max)}$.

@seismicisolation
@seismicisolation

Only if full-scale testing is not possible, reduced-scale prototype specimens can be used to quantify rate-dependent properties of isolators. The reduced-scale prototype specimens shall be of the same type and material and shall be manufactured with the same processes and quality as full-scale prototypes and shall be tested at a frequency that represents full-scale prototype loading rates.

17.8.2.4 Units Dependent on Bilateral Load If the force-deflection properties of the isolator units exhibit bilateral load dependence, the tests specified in Sections 17.8.2.2 and 17.8.2.3 shall be augmented to include bilateral load at the following increments of the maximum displacement, D_M: 0.25 and 1.0, 0.5 and 1.0, 0.67 and 1.0, and 1.0 and 1.0.

If reduced-scale specimens are used to quantify bilateral-load-dependent properties, they shall meet the requirements of Section 17.8.2.7; the reduced-scale specimens shall be of the same type and material and manufactured with the same processes and quality as full-scale prototypes.

The force-deflection properties of an isolator unit shall be considered to be dependent on bilateral load if the effective stiffness when subjected to bilateral loading is different by more than 15% from the effective stiffness subjected to unilateral loading.

17.8.2.5 Maximum and Minimum Vertical Load Isolator units that carry vertical load shall be subjected to one fully reversed cycle of loading at the total maximum displacement, D_{TM}, and at each of the vertical loads corresponding to the maximum and minimum downward vertical loads, as specified in Section 17.2.7.1 on any one isolator of a common type and size. Axial load and displacement values for each test shall be the greater of those determined by analysis using the upper bound and lower bound values of isolation system properties, determined in accordance with Section 17.2.8.5.

EXCEPTION: In lieu of envelope values for a single test, it shall be acceptable to perform two tests, one each for the combination of vertical load and horizontal displacement obtained from analysis using the upper bound and lower bound values of isolation system properties, respectively, determined in accordance with Section 17.2.8.5.

17.8.2.6 Sacrificial Wind-Restraint Systems If a sacrificial wind-restraint system is to be used, its ultimate capacity shall be established by test.

17.8.2.7 Testing Similar Units Prototype tests need not be performed if an isolator unit, when compared to another tested unit, complies with all of the following criteria:

1. The isolator is not more than 15% larger nor more than 30% smaller than the previously tested prototype, in terms of governing device dimensions;
2. The isolator uses the same materials;
3. The isolator has an energy dissipated per cycle, E_{loop}, that is not less than 85% of the previously tested unit;
4. The isolator is fabricated by the same manufacturer using the same or more stringent documented manufacturing and quality control procedures;
5. For elastomeric type isolators, the design shall not be subject to a greater shear strain nor greater vertical stress than that of the previously tested prototype; and
6. For sliding type isolators, the design shall not be subject to a greater vertical stress or sliding velocity than that of the previously tested prototype using the same sliding material.

The prototype testing exemption above shall be approved by independent design review, as specified in Section 17.7.

When the results of tests of similar isolator units are used to establish dynamic properties in accordance with Section 17.8.2.3, in addition to Items 2 through 4, the following criteria shall be satisfied:

7. The similar unit shall be tested at a frequency that represents design full-scale loading rates, in accordance with principles of scaling and similarity; and
8. The length scale of reduced-scale specimens shall not be greater than two.

17.8.3 Determination of Force-Deflection Characteristics The force-deflection characteristics of an isolator unit shall be based on the cyclic load tests of prototype isolators specified in Section 17.8.2.

As required, the effective stiffness of an isolator unit, k_{eff}, shall be calculated for each cycle of loading as prescribed by Equation (17.8-1):

$$k_{\text{eff}} = \frac{|F^+| + |F^-|}{|\Delta^+| + |\Delta^-|} \tag{17.8-1}$$

where F^+ and F^- are the positive and negative forces, at the maximum positive and minimum negative displacements Δ^+ and Δ^-, respectively.

As required, the effective damping, β_{eff}, of an isolator unit shall be calculated for each cycle of loading by Equation (17.8-2):

$$\beta_{\text{eff}} = \frac{2}{\pi} \frac{E_{\text{loop}}}{k_{\text{eff}}(|\Delta^+| + |\Delta^-|)^2} \tag{17.8-2}$$

where the energy dissipated per cycle of loading, E_{loop}, and the effective stiffness, k_{eff}, shall be based on peak test displacements of Δ^+ and Δ^-.

The postyield stiffness, k_d, of each isolator unit shall be calculated for each cycle of loading using the following assumptions:

1. A test loop shall be assumed to have bilinear hysteretic characteristics with values of k_1, k_d, f_o, f_y, k_{eff}, and E_{loop}, as shown in Figure 17.8-1;
2. The computed loop shall have the same values of effective stiffness, k_{eff}, and energy dissipated per cycle of loading, E_{loop}, as the test loop; and
3. The assumed value of k_1 shall be a visual fit to the elastic stiffness of the isolator unit during unloading, immediately after D_M.

It is permitted to use different methods for fitting the loop, such as a straight-line fit of k_d directly to the hysteresis curve extending to D_M and then determining k_1 to match E_{loop}.

17.8.4 Test Specimen Adequacy The performance of the test specimens shall be deemed adequate if all of the following conditions are satisfied:

1. The force-deflection plots for all tests specified in Section 17.8.2 have a positive incremental force-resisting capacity.
2. The average postyield stiffness, k_d, and energy dissipated per cycle, E_{loop}, for the three cycles of test specified in Section 17.8.2.2, Item 3, for the vertical load equal to the average dead load plus one-half the effects caused by live load, including the effects of heating and rate of loading, in

@seismicisolation

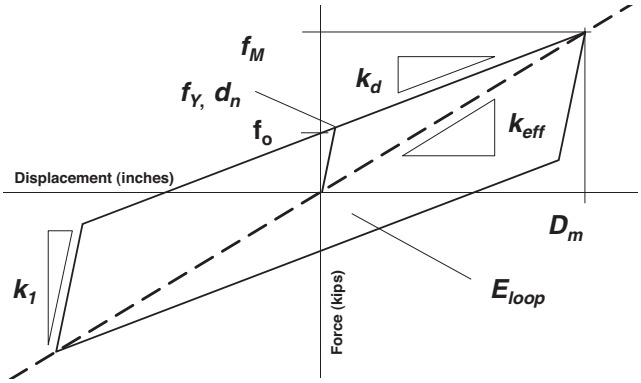

Figure 17.8-1. Nominal properties of the isolator bilinear force-deflection model.

accordance with Section 17.2.8.3, fall within the range of the nominal design values defined by the permissible individual isolator range, which are typically +/−5% greater than the $\lambda_{(spec,min)}$ and $\lambda_{(spec,max)}$ range for the average of all isolators.

3. For each increment of test displacements $0.67D_M$ and $1.0D_M$ specified in Item 2 and Item 3 of Section 17.8.2.2, and for each vertical load case specified in Section 17.8.2.2, the value of the postyield stiffness, k_d, at each of the cycles of test at a common displacement shall fall within the range defined by $\lambda_{(test,min)}$ and $\lambda_{(test,max)}$ multiplied by the nominal value of postyield stiffness.
4. For each specimen, there is no greater than a 20% change in the initial effective stiffness over the cycles of test specified in Item 4 of Section 17.8.2.2.
5. For each test specimen, the value of the postyield stiffness, k_d, and energy dissipated per cycle, E_{loop}, for any cycle of test in Section 17.8.2.2, Item 4(a) shall fall within the range of the nominal design values, defined by $\lambda_{(test,min)}$ and $\lambda_{(test,max)}$.
6. For each specimen, there is no greater than a 20% decrease in the initial effective damping over the cycles of test specified in Item 4 of Section 17.8.2.2.
7. All specimens of vertical load-carrying elements of the isolation system remain stable where tested, in accordance with Section 17.8.2.5.

EXCEPTION: The RDP is permitted to adjust the limits of Items 3, 4, and 6 to account for the property variation factors of Section 17.2.8.4 used for design of the isolation system.

17.8.5 Production Tests A test program for the isolator units used in the construction shall be established by the RDP. The test program shall evaluate the consistency of measured values of nominal isolator unit properties by testing 100% of the isolators in combined compression and shear, at not less than two-thirds of the maximum displacement, D_M, determined using lower bound properties.

The mean results of all tests shall fall within the range of values defined by the $\lambda_{(spec,max)}$ and $\lambda_{(spec,min)}$ values established in Section 17.2.8.4. A different range of values is permitted to be used for individual isolator units and for the average value across all isolators of a given unit type, provided that differences in the ranges of values are accounted for in the design of each element of the isolation system, as prescribed in Section 17.2.8.4.

17.9 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

See Chapter 23 for the list of consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

@seismicisolation
@seismicisolation

CHAPTER 18
SEISMIC DESIGN REQUIREMENTS FOR STRUCTURES WITH DAMPING SYSTEMS

18.1 GENERAL

18.1.1 Scope Every structure with a damping system, and every portion thereof, shall be designed and constructed in accordance with the requirements of this standard, as modified by this chapter. Where damping devices are used across the isolation interface of a seismically isolated structure, displacements, velocities, and accelerations shall be determined in accordance with Chapter 17.

18.1.2 Definitions The following definitions apply only to the structures with damping system provisions of Chapter 18 and are in addition to the definitions presented in Chapter 11.

DAMPING DEVICE: A flexible structural element of the damping system that dissipates energy caused by relative motion of each end of the device. Damping devices include all pins, bolts, gusset plates, brace extensions, and other components required to connect damping devices to the other elements of the structure. Damping devices are classified as either displacement-dependent or velocity-dependent, or a combination thereof, and are permitted to be configured to act in either a linear or nonlinear manner.

DAMPING SYSTEM: The collection of structural elements that includes all the individual damping devices, all structural elements or bracing required to transfer forces from damping devices to the base of the structure, and the structural elements required to transfer forces from damping devices to the seismic force-resisting system.

DISPLACEMENT-DEPENDENT DAMPING DEVICE: The force response of a displacement-dependent damping device is primarily a function of the relative displacement between each end of the device. The response is substantially independent of the relative velocity between each of the devices and/or the excitation frequency.

FORCE-CONTROLLED ELEMENTS: Element actions for which reliable inelastic deformation capacity is not achievable without critical strength decay.

VELOCITY-DEPENDENT DAMPING DEVICE: The force-displacement relation for a velocity-dependent damping device is primarily a function of the relative velocity between each end of the device and could also be a function of the relative displacement between each end of the device.

18.1.3 Symbols Symbols presented in this section apply only to the structures with damping system provisions of Chapter 18 and are in addition to the symbols presented in Chapter 11.

B_{1D} = Numerical coefficient, as set forth in Table 18.7-1, for effective damping equal to $\beta_{mD}(m=1)$ and period of structure equal to T_{1D}

B_{1E} = Numerical coefficient, as set forth in Table 18.7-1, for the effective damping equal to $\beta_I + \beta_{V1}$ and period equal to T_1

B_{1M} = Numerical coefficient, as set forth in Table 18.7-1, for effective damping equal to $\beta_{mM}(m=1)$ and period of structure equal to T_{1M}

B_{mD} = Numerical coefficient, as set forth in Table 18.7-1, for effective damping equal to β_{ml} and period of structure equal to T_m

B_{mM} = Numerical coefficient, as set forth in Table 18.7-1, for effective damping equal to β_{mM} and period of structure equal to T_m

B_R = Numerical coefficient, as set forth in Table 18.7-1, for effective damping equal to β_R and period of structure equal to T_R

B_{V+I} = Numerical coefficient, as set forth in Table 18.7-1, for effective damping equal to the sum of viscous damping in the fundamental mode of vibration of the structure in the direction of interest, $\beta_{Vm}(m=1)$, plus inherent damping, β_I, and period of structure equal to T_1

C_{mFD} = Force coefficient, as set forth in Table 18.7-2

C_{mFV} = Force coefficient, as set forth in Table 18.7-3

C_{S1} = Seismic response coefficient of the fundamental mode of vibration of the structure in the direction of interest, Section 18.7.1.2.4 or 18.7.2.2.4 ($m=1$)

C_{Sm} = Seismic response coefficient of the mth mode of vibration of the structure in the direction of interest, Section 18.7.1.2.4 ($m=1$) or Section 18.7.1.2.6 ($m>1$)

C_{SR} = Seismic response coefficient of the residual mode of vibration of the structure in the direction of interest, Section 18.7.2.2.8

D_{1D} = Fundamental mode design displacement at the center of rigidity of the roof level of the structure in the direction under consideration, Section 18.7.2.3.2

D_{1M} = Fundamental mode MCE_R displacement at the center of rigidity of the roof level of the structure in the direction under consideration, Section 18.7.2.3.5

D_{mD} = Design displacement at the center of rigidity of the roof level of the structure caused by the mth mode of vibration in the direction under consideration, Section 18.7.1.3.2

D_{mM} = MCE_R displacement at the center of rigidity of the roof level of the structure caused by the mth mode of vibration in the direction under consideration, Section 18.7.1.3.5

D_{RD} = Residual mode design displacement at the center of rigidity of the roof level of the structure in the direction under consideration, Section 18.7.2.3.2

D_{RM} = Residual mode MCE_R displacement at the center of rigidity of the roof level of the structure in the direction under consideration, Section 18.7.2.3.5

@seismicisolation
@seismicisolation

D_Y = Displacement at the center of rigidity of the roof level of the structure at the effective yield point of the seismic force-resisting system, Section 18.7.3.3

E_{loop} = Area of one load-displacement hysteresis loop, Section 18.6.2.5

f_i = Lateral force at level i of the structure distributed approximately in accordance with Section 12.8.3, Section 18.7.2.2.3

F_{i1} = Inertial force at level i (or mass point i) in the fundamental mode of vibration of the structure in the direction of interest, Section 18.7.2.2.9

F_{im} = Inertial force at level i (or mass point i) in the mth mode of vibration of the structure in the direction of interest, Section 18.7.1.2.7

F_{iR} = Inertial force at level i (or mass point i) in the residual mode of vibration of the structure in the direction of interest, Section 18.7.2.2.9

h_i = Height above the base to level i, Section 18.7.2.2.3

h_n = Structural height, Section 18.7.2.2.3

q_H = Hysteresis loop adjustment factor, as determined in Section 18.7.3.2.2.1

Q_{DSD} = Force in an element of the damping system required to resist design seismic forces of displacement-dependent damping devices, Section 18.7.4.5

Q_E = Seismic design force in each element of the damping system, Section 18.7.4.5

Q_{mDSV} = Force in an element of the damping system required to resist design seismic forces of velocity-dependent damping devices caused by the mth mode of vibration of the structure in the direction of interest, Section 18.7.4.5

Q_{mSFRS} = Force in an element of the damping system equal to the design seismic force of the mth mode of vibration of the structure in the direction of interest, Section 18.7.4.5

T_1 = Fundamental period of the structure in the direction under consideration

T_{1D} = Effective period, in seconds, of the fundamental mode of vibration of the structure at the design displacement in the direction under consideration, as prescribed by Section 18.7.1.2.5 or 18.7.2.2.5

T_{1M} = Effective period, in seconds, of the fundamental mode of vibration of the structure at the MCE_R displacement in the direction under consideration, as prescribed by Section 18.7.1.2.5 or 18.7.2.2.5

T_m = Period, in seconds, of the mth mode of vibration of the structure in the direction under consideration, Section 18.7.1.2.6

T_R = Period, in seconds, of the residual mode of vibration of the structure in the direction under consideration, Section 18.7.2.2.7

V = Seismic base shear in the direction of interest, Section 18.2.1.1

V_1 = Design value of the seismic base shear of the fundamental mode in a given direction of response, as determined in Sections 18.7.2.2.1 and 18.7.2.2.2,

V_m = Design value of the seismic base shear of the mth mode of vibration of the structure in the direction of interest, Section 18.7.1.2.2

V_{min} = Minimum allowable value of base shear permitted for design of the seismic force-resisting system of the structure in the direction of interest, Section 18.2.1.1

V_R = Design value of the seismic base shear of the residual mode of vibration of the structure in a given direction, as determined in Section 18.7.2.2.6

w_i = Effective seismic weight of the ith floor of the structure, Section 18.7.1.2.2

$\overline{W}_1$ = Effective fundamental mode seismic weight, determined in accordance with Equation (18.7-2b) for $m = 1$

$\overline{W}_m$ = Effective seismic weight of the mth mode of vibration of the structure, Section 18.7.1.2.2

W_m = Maximum strain energy in the mth mode of vibration of the structure in the direction of interest at modal displacements, δ_{im}, Section 18.7.3.2.2.1

W_{mj} = Work done by jth damping device in one complete cycle of dynamic response corresponding to the mth mode of vibration of the structure in the direction of interest at modal displacements, δ_{im}, Section 18.7.3.2.2.1

$\overline{W}_R$ = Effective residual mode seismic weight, determined in accordance with Equation (18.7-30)

α = Velocity exponent relating damping device force to damping device velocity

β_{HD} = Component of effective damping of the structure in the direction of interest caused by postyield hysteretic behavior of the seismic force-resisting system and elements of the damping system at effective ductility demand, μ_D, Section 18.7.3.2.2

β_{HM} = Component of effective damping of the structure in the direction of interest caused by postyield hysteretic behavior of the seismic force-resisting system and elements of the damping system at effective ductility demand, μ_M, Section 18.7.3.2.2

β_I = Component of effective damping of the structure caused by the inherent dissipation of energy by elements of the structure, at or just below the effective yield displacement of the seismic force-resisting system, Section 18.7.3.2.1

β_{mD} = Total effective damping of the mth mode of vibration of the structure in the direction of interest at the design displacement, Section 18.7.3.2

β_{mM} = Total effective damping of the mth mode of vibration of the structure in the direction of interest at the MCE_R displacement, Section 18.7.3.2

β_R = Total effective damping in the residual mode of vibration of the structure in the direction of interest, calculated in accordance with Section 18.7.3.2 (using $\mu_D = 1.0$ and $\mu_M = 1.0$)

β_{Vm} = Component of effective damping of the mth mode of vibration of the structure in the direction of interest caused by viscous dissipation of energy by the damping system, at or just below the effective yield displacement of the seismic force-resisting system, Section 18.7.3.2.3

Γ_1 = Participation factor of the fundamental mode of vibration of the structure in the direction of interest, Section 18.7.1.2.3 or 18.7.2.2.3 ($m = 1$)

Γ_m = Participation factor in the mth mode of vibration of the structure in the direction of interest, Section 18.7.1.2.3

Γ_R = Participation factor of the residual mode of vibration of the structure in the direction of interest, Section 18.7.2.2.7

δ_i = Elastic deflection of level i of the structure caused by applied lateral force, f_i, Section 18.7.2.2.3

δ_{i1D} = Fundamental mode design deflection of level i at the center of rigidity of the structure in the direction under consideration, Section 18.7.2.3.1

δ_{iD} = Total design deflection of level i at the center of rigidity of the structure in the direction under consideration, Section 18.7.2.3

@seismicisolation
@seismicisolation

δ_{iM} = Total MCE_R deflection of level i at the center of rigidity of the structure in the direction under consideration, Section 18.7.2.3

δ_{im} = Deflection of level i in the mth mode of vibration at the center of rigidity of the structure in the direction under consideration, Section 18.7.3.2.3

δ_{imD} = Design deflection of level i in the mth mode of vibration at the center of rigidity of the structure in the direction under consideration, Section 18.7.1.3.1

δ_{iRD} = Residual mode design deflection of level i at the center of rigidity of the structure in the direction under consideration, Section 18.7.2.3.1

Δ_{1D} = Design story drift caused by the fundamental mode of vibration of the structure in the direction of interest, Section 18.7.2.3.3

Δ_D = Total design story drift of the structure in the direction of interest, Section 18.7.2.3.3

Δ_M = Total MCE_R story drift of the structure in the direction of interest, Section 18.7.2.3

Δ_{mD} = Design story drift caused by the mth mode of vibration of the structure in the direction of interest, Section 18.7.1.3.3

Δ_{RD} = Design story drift caused by the residual mode of vibration of the structure in the direction of interest, Section 18.7.2.3.3

$\lambda_{(ae,\max)}$ = Factor to represent possible variation in damper properties above the tested values caused by aging and environmental effects; this is a multiple of all the individual aging and environmental effects, Section 18.2.4.5

$\lambda_{(ae,\min)}$ = Factor to represent possible variation in damper properties below the tested values caused by aging and environmental effects; this is a multiple of all the individual aging and environmental effects, Section 18.2.4.5

$\lambda_{\max}$ = Factor to represent possible total variation in damper properties above the nominal properties, Section 18.2.4.5

$\lambda_{\min}$ = Factor to represent possible total variation in damper properties below the nominal properties, Section 18.2.4.5

$\lambda_{(spec,\max)}$ = Factor to represent permissible variation in production damper nominal properties above those assumed in design, Section 18.2.4.5

$\lambda_{(spec,\min)}$ = Factor to represent permissible variation in production damper nominal properties below those assumed in design, Section 18.2.4.5

$\lambda_{(test,\max)}$ = Factor to represent possible variations in damper properties above the nominal values obtained from the prototype tests; this is a multiple of all the testing effects, Section 18.2.4.5

$\lambda_{(test,\min)}$ = Factor to represent possible variations in damper properties below the nominal values obtained from the prototype tests; this is a multiple of all the testing effects, Section 18.2.4.5

μ = Effective ductility demand on the seismic force-resisting system in the direction of interest

μ_D = Effective ductility demand on the seismic force-resisting system in the direction of interest caused by the design earthquake ground motions, Section 18.7.3.3

μ_M = Effective ductility demand on the seismic force-resisting system in the direction of interest caused by the MCE_R ground motions, Section 18.7.3.3

$\mu_{\max}$ = Maximum allowable effective ductility demand on the seismic force-resisting system caused by the design earthquake ground motions, Section 18.7.3.4

ϕ_{i1} = Displacement amplitude at level i of the fundamental mode of vibration of the structure in the direction of interest, normalized to unity at the roof level, Section 18.7.2.2.3

ϕ_{im} = Displacement amplitude at level i of the mth mode of vibration of the structure in the direction of interest, normalized to unity at the roof level, Section 18.7.1.2.2

ϕ_{iR} = Displacement amplitude at level i of the residual mode of vibration of the structure in the direction of interest normalized to unity at the roof level, Section 18.7.2.2.7

∇_{1D} = Design story velocity caused by the fundamental mode of vibration of the structure in the direction of interest, Section 18.7.2.3.4

∇_D = Total design story velocity of the structure in the direction of interest, Section 18.7.1.3.4

∇_M = Total MCE_R story velocity of the structure in the direction of interest, Section 18.7.2.3

∇_{mD} = Design story velocity caused by the mth mode of vibration of the structure in the direction of interest, Section 18.7.1.3.4

∇_{RD} = Design story velocity caused by the residual mode of vibration of the structure in the direction of interest, Section 18.7.2.3.4

18.2 GENERAL DESIGN REQUIREMENTS

18.2.1 System Requirements Design of the structure shall consider the basic requirements for the seismic force-resisting system and the damping system, as defined in the following sections. The seismic force-resisting system shall have the required strength to meet the forces defined in Section 18.2.1.1. The combination of the seismic force-resisting system and the damping system is permitted to be used to meet the drift requirement.

18.2.1.1 Seismic Force-Resisting System Structures that contain a damping system shall have a seismic force-resisting system that, in each lateral direction, conforms to one of the types indicated in Table 12.2-1.

The design of the seismic force-resisting system in each direction shall satisfy the minimum base shear requirements of this section and the requirements of Section 18.4, if the nonlinear response history procedure of Section 18.3 is used, or Section 18.7.4, if either the response spectrum procedure of Section 18.7.1 or the equivalent lateral force procedure of Section 18.7.2 is used.

The seismic base shear used for design of the seismic force-resisting system shall not be less than $V_{\min}$, where $V_{\min}$ is determined as the greater of the values computed using Equations (18.2-1) and (18.2-2):

$$V_{\min} = \frac{V}{B_{V+1}} \tag{18.2-1}$$

$$V_{\min} = 0.75V \tag{18.2-2}$$

where V is the seismic base shear in the direction of interest, determined in accordance with Section 12.8, and B_{V+I} is the numerical coefficient, as set forth in Table 18.7-1, for effective damping equal to the sum of viscous damping in the fundamental

@seismicisolation
@seismicisolation

mode of vibration of the structure in the direction of interest, $\beta_{Vm}(m=1)$, plus inherent damping, β_I, and period of structure equal to T_1.

EXCEPTION: The seismic base shear used for design of the seismic force-resisting system shall not be taken as less than $1.0V$ if either of the following conditions apply:

1. In the direction of interest, the damping system has fewer than two damping devices on each floor level, configured to resist torsion.
2. The seismic force-resisting system has Torsional Irregularity Ratio $TIR > 1.4$, or vertical irregularity Type 1b (Table 12.3-2).

18.2.1.2 Damping System Damping devices and all other components required to connect damping devices to the other elements of the structure shall be designed to remain elastic for MCE_R loads. Other elements of the damping system are permitted to have inelastic response at MCE_R if it is shown by analysis or test that inelastic response of these elements would not adversely affect damping system function. If either the response spectrum procedure of Section 18.7.1 or the equivalent lateral force procedure of Section 18.7.2 is used, the inelastic response shall be limited, in accordance with the requirements of Section 18.7.4.6.

Force-controlled elements of the damping system shall be designed for seismic forces that are increased by 20% from those corresponding to average MCE_R response.

18.2.2 Seismic Hazard

18.2.2.1 Spectral Response Acceleration Parameters and Response Spectrum The design earthquake and MCE_R spectral response acceleration parameters (S_{DS}, S_{D1}, S_{MS}, and S_{M1}) and the design earthquake and MCE_R spectra shall be determined in accordance with Section 11.4.

18.2.2.2 Ground Motions for Response History Analysis Where response history analysis in accordance with Section 18.3 is used to design structures with damping systems, the provisions of Section 16.2 shall apply. For establishing the period range in Section 16.2.3.1, nominal properties of damping devices at the MCE_R per Section 18.2.4.4 shall be assumed. Design earthquake ground motions shall be taken as two-thirds times MCE_R ground motions.

18.2.3 Procedure Selection Structures with a damping system provided for seismic resistance shall be analyzed and designed using the nonlinear response history procedure of Section 18.3.

EXCEPTION: It shall be permitted to analyze and design the structure using the response spectrum procedure of Section 18.7.1, subject to the limits of Section 18.2.3.1 or the equivalent lateral force procedure of Section 18.7.2, subject to the limits of Section 18.2.3.2.

18.2.3.1 Response Spectrum Procedure The response spectrum procedure of Section 18.7.1 is permitted to be used for analysis and design provided all the following conditions apply:

1. In each principal direction, the damping system has at least two damping devices in each story, configured to resist torsion; and
2. The total effective damping of the fundamental mode, $\beta_{mD}(m=1)$, of the structure in the direction of interest is not greater than 35% of critical.

18.2.3.2 Equivalent Lateral Force Procedure The equivalent lateral force procedure of Section 18.7.2 is permitted to be used for analysis and design, provided all the following conditions apply:

1. In each principal direction, the damping system has at least two damping devices in each story, configured to resist torsion.
2. The total effective damping of the fundamental mode, $\beta_{mD}(m=1)$, of the structure in the direction of interest is not greater than 35% of critical.
3. The seismic force-resisting system does not have horizontal irregularity Type 1a or 1b (Table 12.3-1) or vertical irregularity Type 1 or 2 (Table 12.3-2).
4. Floor diaphragms are rigid, as defined in Section 12.3.1.
5. The height of the structure above the base does not exceed 100 ft (30 m).

18.2.4 Damping System

18.2.4.1 Device Design The design, construction, and installation of damping devices shall be based on response to MCE_R ground motions and consideration of all of the following:

1. Low-cycle, large-displacement degradation caused by seismic loads.
2. High-cycle, small-displacement degradation caused by wind, thermal, or other cyclic loads.
3. Forces or displacements caused by gravity loads.
4. Adhesion of device parts caused by corrosion or abrasion, biodegradation, moisture, or chemical exposure.
5. Exposure to environmental conditions, including, but not limited to, temperature, humidity, moisture, radiation (e.g., ultraviolet light), and reactive or corrosive substances (e.g., saltwater).

Devices using bimetallic interfaces subject to cold welding of the sliding interface shall be prohibited from use in a damping system.

Damping devices subject to failure by low-cycle fatigue shall resist wind forces without slip, movement, or inelastic cycling.

The design of damping devices shall incorporate the range of thermal conditions, device wear, manufacturing tolerances, and other effects that cause device properties to vary during the design life of the device, in accordance with Section 18.2.4.4. Ambient temperature shall be the normal in-service temperature of the damping device. The design temperature range shall cover the annual minimum and maximum in-service temperatures of the damping device.

18.2.4.2 Multiaxis Movement Connection points of damping devices shall provide sufficient articulation to accommodate simultaneous longitudinal, lateral, and vertical displacements of the damping system.

18.2.4.3 Inspection and Periodic Testing Means of access for the inspection and removal of all damping devices shall be provided.

The registered design professional (RDP) responsible for design of the structure shall establish an inspection, maintenance, and testing schedule for each type of damping device to ensure that the devices respond in a dependable manner throughout their design life. The degree of inspection and testing shall reflect the established in-service history of the damping devices and the likelihood of change in properties over the design life of the devices.

@seismicisolation
@seismicisolation

18.2.4.4 Nominal Design Properties Nominal design properties for energy-dissipation devices shall be established from either project-specific prototype test data or prior prototype tests on devices of a similar type and size. The nominal design properties shall be based on data from prototype tests specified in Section 18.6.2.2 (2) and determined by Section 18.6.2.4 (2). These nominal design properties shall be modified by property variation or lambda (λ) factors, as specified in Section 18.2.4.5.

18.2.4.5 Maximum and Minimum Damper Properties Maximum and minimum property modification (λ) factors shall be used to account for variation of the nominal design parameters of each damping device type for the effects of heating caused by cyclic dynamic motion, loading rate, duration of seismic and wind loading, variability and uncertainty in production device properties, operating temperature, aging, environmental exposure, and contamination. Manufacturer-specific qualification test data, in accordance with Section 18.6.1.1 and prototype test data in accordance with Section 18.6.2, shall be used to develop the property modification factors.

Maximum and minimum property modification (λ) factors shall be established, in accordance with Equations (18.2-3a) and (18.2-3b) for each device, by the RDP and used in analysis and design to account for the variation from nominal properties:

$$\lambda_{max} = [(1 + (0.75 \times (\lambda_{(ae,max)} - 1))) \times \lambda_{(test,max)} \times \lambda_{(spec,max)}] \geq 1.2 \quad (18.2\text{-}3a)$$

$$\lambda_{min} = [(1 - (0.75 \times (1 - \lambda_{(ae,min)}))) \times \lambda_{(test,min)} \times \lambda_{(spec,min)}] \leq 0.85 \quad (18.2\text{-}3b)$$

where

$\lambda_{(ae,max)}$ = Factor to represent possible variation in damper properties above the nominal values caused by aging and environmental effects; this is a multiple of all the individual aging and environmental effects;

$\lambda_{(ae,min)}$ = Factor to represent possible variation in damper properties below the nominal values caused by aging and environmental effects; this is a multiple of all the individual aging and environmental effects;

$\lambda_{(test,max)}$ = Factor to represent possible variations in damper properties above the nominal values obtained from the prototype tests; this is a multiple of all the testing effects;

$\lambda_{(test,min)}$ = Factor to represent possible variations in damper properties below the nominal values obtained from the prototype tests; this is a multiple of all the testing effects;

$\lambda_{(spec,max)}$ = Factor established by the RDP to represent permissible variation in production damper properties above the nominal values; and

$\lambda_{(spec,min)}$ = Factor established by the RDP to represent permissible variation in production damper properties below the nominal values.

EXCEPTION: With test data reviewed by the RDP and accepted by peer review, it is permitted to use λ_{max} less than 1.2 and λ_{min} greater than 0.85.

Maximum and minimum analysis and design properties for each device shall be determined in accordance with Equations (18.2-4a) and (18.2-4b), for each modeling parameter as follows:

$$\text{Maximum design property} = \text{nominal design property} \times \lambda_{max} \quad (18.2\text{-}4a)$$

$$\text{Minimum design property} = \text{nominal design property} \times \lambda_{min} \quad (18.2\text{-}4b)$$

A maximum and minimum analysis and design property shall be established for each modeling parameter as necessary for the selected method of analysis. Maximum velocity coefficients, stiffness, strength, and energy dissipation shall be considered together as the maximum analysis and design case, and minimum velocity coefficients, strength, stiffness, and energy dissipation shall be considered together as the minimum analysis and design case.

Separate maximum and minimum properties shall be established for loads and displacements corresponding to the design level conditions and the MCE_R conditions.

18.2.4.6 Damping System Redundancy If fewer than four energy-dissipation devices are provided in any story of a building in either principal direction, or fewer than two devices are located on each side of the center of stiffness of any story in either principal direction, all energy-dissipation devices shall be capable of sustaining displacements equal to 130% of the maximum calculated displacement in the device under MCE_R. A velocity-dependent device shall be capable of sustaining the force and displacement associated with a velocity equal to 130% of the maximum calculated velocity for that device under MCE_R.

18.3 NONLINEAR RESPONSE HISTORY PROCEDURE

The stiffness and damping properties of the damping devices used in the models shall be based on or verified by testing of the damping devices, as specified in Section 18.6. The nonlinear force-velocity-displacement characteristics of damping devices shall be modeled, as required, to explicitly account for device dependence on frequency, amplitude, and duration of seismic loading.

A nonlinear response history analysis shall use a mathematical model of the seismic force-resisting system and the damping system, as provided in this section. The model shall directly account for the nonlinear hysteretic behavior of all members and connections undergoing inelastic behavior, in a manner consistent with applicable laboratory test data. Test data shall not be extrapolated beyond tested deformation levels. If the analysis results indicate that degradation in element strength or stiffness can occur, the hysteretic models shall include these effects.

EXCEPTION: If the calculated force in an element of the seismic force-resisting system or the damping system does not exceed 1.5 times its expected strength using strength reduction factor $\phi = 1$, that element is permitted to be modeled as linear.

Inherent damping of the structure shall not be taken as greater than 3% of critical unless test data consistent with levels of deformation at or just below the effective yield displacement of the seismic force-resisting system support higher values.

Analysis shall be performed at both the design earthquake and at the MCE_R earthquake levels. The design earthquake analysis need not include the effects of accidental eccentricity. Results from the design earthquake analysis shall be used to design the

@seismicisolation

seismic force-resisting system. Results from the MCE_R analysis shall be used to design the damping system.

18.3.1 Damping Device Modeling Mathematical models of displacement-dependent damping devices shall include the hysteretic behavior of the devices consistent with test data and accounting for all significant changes in strength, stiffness, and hysteretic loop shape. Mathematical models of velocity-dependent damping devices shall include the velocity coefficient consistent with test data. If damping device properties change with time and/or temperature, such behavior shall be modeled explicitly. The flexible elements of damping devices connecting damper units to the structure shall be included in the model.

EXCEPTION: If the properties of the damping devices are expected to change during the duration of the response history analysis, the dynamic response is permitted to be enveloped by the maximum and minimum device properties from Section 18.2.4.5. All these limit cases for variable device properties shall satisfy the same conditions as if the time-dependent behavior of the devices were explicitly modeled.

18.3.2 Accidental Mass Eccentricity Inherent eccentricity resulting from lack of symmetry in mass and stiffness shall be accounted for in the MCE_R analysis. In addition, accidental eccentricity consisting of displacement of the center of mass from the computed location by an amount equal to 5% of the diaphragm dimension separately, in each of two orthogonal directions at each diaphragm level, shall be accounted for in the analysis.

EXCEPTION: It is permitted to account for the effects of accidental eccentricity through the establishment of amplification factors on forces, drifts, and deformations that permit results determined from an analysis, using only the computed center-of-mass configuration to be scaled to bound the results of all the mass-eccentric cases.

18.3.3 Response Parameters Maximum values of each response parameter of interest shall be calculated for each ground motion used for the response history analysis. Response parameters shall include the forces, displacements, and velocities (in the case of velocity-dependent devices) in each discrete damping device. The average value of a response parameter of interest across the suite of design earthquake or MCE_R motions is permitted to be used for design.

18.4 SEISMIC LOAD CONDITIONS AND ACCEPTANCE CRITERIA FOR NONLINEAR RESPONSE HISTORY PROCEDURE

For the nonlinear response history procedure of Section 18.3, the seismic force-resisting system, damping system, loading conditions, and acceptance criteria for response parameters of interest shall conform with the requirements of the following subsections.

18.4.1 Seismic Force-Resisting System The seismic force-resisting system shall satisfy the strength requirements of Section 12.2.1 using both

1. The seismic base shear, V_{min}, as given by Section 18.2.1.1, and
2. The demands from the design earthquake nonlinear response history analysis.

The story drifts shall be determined using the MCE_R ground motions with the combined model of the seismic force-resisting system and the damping system. Accidental eccentricity shall be included.

The maximum drift at MCE_R shall neither exceed 3%, nor the drift limits specified in Table 12.12-1 times the smaller of $1.5R/C_d$ and 1.9. C_d and R shall be taken from Table 12.2-1 for the building framing under consideration.

18.4.2 Damping System The damping devices and their connections shall be sized to resist the forces, displacements, and velocities from the MCE_R ground motions. Force-controlled elements of the damping system shall be designed for seismic forces that are increased by 20% from those corresponding to the average MCE_R response.

18.4.3 Combination of Load Effects The effects on the damping system caused by gravity loads and seismic forces shall be combined, in accordance with Section 12.4, using the effect of horizontal seismic forces, Q_E, except that Q_E shall be determined in accordance with the MCE_R analysis. When load combinations are used that include live loading, it is permitted to use a load factor of 25% on live load for nonlinear response history analysis. The redundancy factor, ρ, shall be taken equal to 1.0 in all cases, and the seismic load effect, including overstrength of Section 12.4.3, need not apply to the design of the damping system.

18.4.4 Acceptance Criteria for the Response Parameters of Interest The damping system components shall be evaluated by the strength design criteria of this standard using the seismic forces and seismic loading conditions determined from the MCE_R nonlinear response history analyses and strength reduction factor $\phi = 1.0$.

18.5 DESIGN REVIEW

An independent design review of the damping system and related test programs shall be performed by one or more individuals possessing knowledge of the subsequent items; a minimum of one reviewer shall be a RDP. Damping system design review shall include, but need not be limited to, all of the following:

1. Project design criteria including site-specific spectra and ground motion histories;
2. Preliminary design of the seismic force-resisting system and the damping system, including selection of the devices and their design parameters;
3. Review of manufacturer test data and property modification factors for the manufacturer and device selected;
4. Prototype testing program (Section 18.6.2);
5. Final design of the entire structural system and supporting analyses, including modeling of the damping devices for response history analysis, if performed; and
6. Damping device production testing program (Section 18.6.3).

18.6 TESTING

18.6.1 General The force-velocity-displacement relationships and damping properties, assumed as the damping device nominal design properties in Section 18.2.4.4, shall be confirmed by the tests conducted in accordance with Section 18.6.2 or shall be based on prior tests of devices meeting the similarity requirements of Section 18.6.2.3.

The prototype tests specified in Section 18.6.2 shall be conducted to confirm the force-velocity-displacement properties of the damping devices assumed for analysis and design and to demonstrate the robustness of individual devices under seismic

@seismicisolation

excitation. These tests shall be conducted prior to production of devices for construction.

The production testing requirements are specified in Section 18.6.3.

Device nominal properties determined from the prototype testing shall meet the acceptance criteria established using $\lambda_{(spec,max)}$ and $\lambda_{(spec,min)}$ from Section 18.2.4.5. These criteria shall account for likely variations in material properties.

Device nominal properties determined from the production testing of Section 18.6.3 shall meet the acceptance criteria established using $\lambda_{(spec,max)}$ and $\lambda_{(spec,min)}$ from Section 18.2.4.5.

The fabrication and quality control procedures used for all prototype and production devices shall be identical. These procedures shall be approved by the RDP prior to the fabrication of prototype devices.

18.6.1.1 Qualification Tests Damping device manufacturers shall submit, for approval by the RDP, the results of qualification tests, analysis of test data, and supporting studies used to quantify the effects of heating caused by cyclic dynamic motion, loading rate, duration of seismic and wind loading, variability and uncertainty in production device properties, operating temperature, aging, environmental exposure, and contamination. The qualification testing shall be applicable to the component types, materials, and force-velocity-displacement response to be used in the proposed construction.

18.6.2 Prototype Tests The following tests shall be performed separately on two full-size damping devices of each type and size used in the design, in the order listed as follows.

Representative sizes of each type of device are permitted to be used for prototype testing, provided that both of the following conditions are met:

1. Fabrication and quality control procedures are identical for each type and size of device used in the structure.
2. Prototype testing of representative sizes is approved by the RDP responsible for the design of the structure.

Test specimens shall not be used for construction unless they are approved by the RDP responsible for the design of the structure and meet the requirements for prototype and production tests.

18.6.2.1 Data Recording The force-deflection relationship for each cycle of each test shall be recorded electronically.

18.6.2.2 Sequence and Cycles of Testing For all the following test sequences, each damping device shall be subjected to gravity load effects and thermal environments representative of the installed condition. For seismic testing, the displacement in the devices calculated for the MCE_R ground motions, termed herein as the maximum device displacement, shall be used.

Prior to the sequence of prototype tests defined in this section, a production test, in accordance with Section 18.6.3, shall be performed, and data from this test shall be used as a baseline for comparison with subsequent tests on production dampers.

1. Each damping device shall be subjected to the number of cycles expected in the design windstorm, but not less than 2,000 continuous fully reversed cycles of wind load. Wind load shall be at amplitudes expected in the design windstorm and shall be applied at a frequency equal to the inverse of the fundamental period of the structure, $1/T_1$.

   It is permitted to use alternate loading protocols, representative of the design windstorm, that apportion the total wind displacement into its expected static, pseudostatic, and dynamic components.

   EXCEPTION: Damping devices need not be subjected to these tests if they are not subject to wind-induced forces or displacements, or if the design wind force is less than the device yield or slip force.
2. Each damping device shall be brought to ambient temperature and loaded with the following sequence of fully reversed, sinusoidal cycles at a frequency equal to $1/(1.5T_1)$:
   (a) Ten fully reversed cycles at the displacement in the energy-dissipation device, corresponding to 0.33 times the MCE_R device displacement;
   (b) Five fully reversed cycles at the displacement in the energy-dissipation device, corresponding to 0.67 times the MCE_R device displacement;
   (c) Three fully reversed cycles at the displacement in the energy-dissipation device, corresponding to 1.0 times the MCE_R device displacement; and
   (d) (d) Where test (c) produces a force in the energy-dissipation device that is less than the MCE_R force in the device from analysis, test (c) shall be repeated at a frequency that produces a force equal to, or greater than, the MCE_R force from analysis.
3. Where the damping device characteristics vary with operating temperature, the tests of Section 18.6.2.2, 2(a) through 2(d) shall be conducted on at least one device at a minimum of two additional temperatures (minimum and maximum) that bracket the design temperature range.

   EXCEPTION: Damping devices are permitted to be tested by alternative methods, provided all the following conditions are met:
   (a) Alternative methods of testing are equivalent to the cyclic testing requirements of this section.
   (b) Alternative methods capture the dependence of the damping device response on ambient temperature, frequency of loading, and temperature rise during testing.
   (c) Alternative methods are approved by the RDP responsible for the design of the structure.
4. If the force-deformation properties of the damping device at any displacement less than or equal to the maximum device displacement change by more than 15% for changes in testing frequency from $1/(1.5T_1)$ to $2.5/T_1$, then the preceding tests [2(a) through 2(c)] shall also be performed at frequencies equal to $1/T_1$ and $2.5/T_1$.

EXCEPTION: When full-scale dynamic testing is not possible because of test machine limitations, it is permitted to use reduced-scale prototypes to qualify the rate-dependent properties of damping devices, provided scaling principles and similitude are used in the design of the reduced-scale devices and the test protocol.

18.6.2.3 Testing Similar Devices Prototype tests need not be performed on a particular damping device if a previously prototype-tested unit exists that meets all the following conditions:

1. It is of similar dimensional characteristics, internal construction, and static and dynamic internal pressures (if any) to the subject damping device; and
2. It is of the same type and materials as the subject damping device; and

@seismicisolation

3. It was fabricated using identical documented manufacturing and quality control procedures that govern the subject damping device; and
4. It was tested under similar maximum strokes and forces to those required of the subject damping device.

18.6.2.4 Determination of Force-Velocity-Displacement Characteristics The force-velocity-displacement characteristics of the prototype damping device shall be based on the cyclic displacement tests specified in Section 18.6.2.2 and all the following requirements:

1. The maximum force and minimum force at zero displacement, the maximum force and minimum force at maximum device displacement, and the area of hysteresis loop (E_{loop}) shall be calculated for each cycle of deformation. Where required, the effective stiffness of a damping device shall be calculated for each cycle of deformation using Equation (17.8-1).
2. Damping device nominal test properties for analysis and design shall be based on the average value for the first three cycles of test at a given displacement. For each cycle of each test, corresponding lambda factors (λ_{test}) for cyclic effects shall be established by comparison of nominal and per-cycle properties.
3. Lambda (λ) factors for velocity and temperature shall be determined simultaneously with those for cyclic effects where full-scale prototype test data are available. Where these or similar effects are determined from separate tests, lambda factors shall be established by the comparison of properties determined under prototype test conditions with corresponding properties determined under the range of test conditions applicable to the property variation parameter.

18.6.2.5 Device Adequacy The performance of a prototype damping device shall be deemed adequate if all the conditions listed as follows are satisfied. The 15% limits specified in the following text are permitted to be increased by the RDP responsible for the design of the structure, provided that the increased limit has been demonstrated by analysis not to have a deleterious effect on the response of the structure.

18.6.2.5.1 Displacement-Dependent Damping Devices The performance of the prototype displacement-dependent damping devices shall be deemed adequate if all the following conditions, based on tests specified in Section 18.6.2.2, are satisfied:

1. For Test 1, no signs of damage including leakage, yielding, or breakage.
2. For Tests 2, 3, and 4, the maximum force and minimum force at zero displacement for a damping device for any one cycle does not differ by more than 15% from the average maximum and minimum forces at zero displacement, as calculated from all cycles in that test at a specific frequency and temperature.
3. For Tests 2, 3, and 4, the maximum force and minimum force at maximum device displacement for a damping device for any one cycle does not differ by more than 15% from the average maximum and minimum forces at the maximum device displacement, as calculated from all cycles in that test at a specific frequency and temperature.
4. For Tests 2, 3, and 4, the area of hysteresis loop (E_{loop}) of a damping device for any one cycle does not differ by more than 15% from the average area of the hysteresis loop, as calculated from all cycles in that test at a specific frequency and temperature.
5. The average maximum and minimum forces at zero displacement and maximum displacement, and the average area of the hysteresis loop (E_{loop}), as calculated for each test in the sequence of Tests 2, 3, and 4, shall not differ by more than 15% from the target values specified by the RDP responsible for the design of the structure.
6. The average maximum and minimum forces at zero displacement and the maximum displacement, and the average area of the hysteresis loop (E_{loop}), as calculated for Test 2(c), shall fall within the limits specified by the RDP, as described by the nominal properties and the lambda factor for specification tolerance ($\lambda_{(spec,max)}$ and $\lambda_{(spec,min)}$) from Section 18.2.4.5.
7. The test lambda factors for damping units, determined in accordance with Section 18.6.2.4, shall not exceed the values specified by the RDP, in accordance with Section 18.2.4.5.

18.6.2.5.2 Velocity-Dependent Damping Devices The performance of the prototype velocity-dependent damping devices shall be deemed adequate if all the following conditions, based on tests specified in Section 18.6.2.2, are satisfied:

1. For Test 1, no signs of damage including leakage, yielding, or breakage.
2. For velocity-dependent damping devices with stiffness, the effective stiffness of a damping device in any one cycle of Tests 2, 3, and 4 does not differ by more than 15% from the average effective stiffness, as calculated from all cycles in that test at a specific frequency and temperature.
3. For Tests 2, 3, and 4, the maximum force and minimum force at zero displacement for a damping device for any one cycle does not differ by more than 15% from the average maximum and minimum forces at zero displacement, as calculated from all cycles in that test at a specific frequency and temperature.
4. For Tests 2, 3, and 4, the area of hysteresis loop (E_{loop}) of a damping device for any one cycle does not differ by more than 15% from the average area of the hysteresis loop, as calculated from all cycles in that test at a specific frequency and temperature.
5. The average maximum and minimum forces at zero displacement, effective stiffness (for damping devices with stiffness only), and average area of the hysteresis loop (E_{loop}), calculated for Test 2(c), shall fall within the limits specified by the RDP, as described by the nominal properties and the lambda factor for specification tolerance ($\lambda_{(spec,max)}$ and $\lambda_{(spec,min)}$) from Section 18.2.4.5.
6. The test lambda factors for damping units determined in accordance with Section 18.6.2.4 shall not exceed the values specified by the RDP, in accordance with Section 18.2.4.5.

18.6.3 Production Tests Prior to installation in a building, damping devices shall be tested in accordance with the requirements of this section.

A test program for the production damping devices shall be established by the RDP. The test program shall validate the nominal properties by testing 100% of the devices for three cycles at 0.67 times the MCE_R stroke at a frequency equal to $1/(1.5T_1)$. The measured values of the nominal properties shall

@seismicisolation
@seismicisolation

fall within the limits provided in the project specifications. These limits shall agree with the specification tolerances on nominal design properties established in Section 18.2.4.5.

EXCEPTION: Production damping devices need not be subjected to this test program if it can be shown by other means that their properties meet the requirements of the project specifications. In such cases, the RDP shall establish an alternative program to ensure the quality of the installed damping devices. This alternative program shall include production testing of at least one device of each type and size unless project-specific prototype tests have been conducted on that identical device type and size. Devices that undergo inelastic action, or are otherwise damaged during this test, shall not be used in construction.

18.7 ALTERNATE PROCEDURES AND CORRESPONDING ACCEPTANCE CRITERIA

Structures analyzed by the response spectrum procedure shall meet the requirements of Sections 18.7.1, 18.7.3, and 18.7.4. Structures analyzed by the equivalent lateral force procedure shall meet the requirements of Sections 18.7.2, 18.7.3, and 18.7.4.

Table 18.7-1. Damping Coefficient, B_{V+I}, B_{1D}, B_{1E}, B_R, B_{1M}, B_{mD}, B_{mM} (Where Period of the Structure $\geq T_0$).

≥100	4.0

18.7.1 Response Spectrum Procedure Where the response spectrum procedure is used to analyze a structure with a damping system, the requirements of this section shall apply.

18.7.1.1 Modeling A mathematical model of the seismic force-resisting system and damping system shall be constructed that represents the spatial distribution of mass, stiffness, and damping throughout the structure. The model and analysis shall comply with the requirements of Section 12.9 for the seismic force-resisting system and with the requirements of this section for the damping system. The stiffness and damping properties of the damping devices used in the models shall be based on or verified by testing of the damping devices, as specified in Section 18.6.

The elastic stiffness of elements of the damping system other than damping devices shall be explicitly modeled. Stiffness of damping devices shall be modeled depending on damping device type as follows:

1. For displacement-dependent damping devices: Displacement-dependent damping devices shall be modeled with an effective stiffness that represents damping device force at the response displacement of interest (e.g., design story drift). Alternatively, the stiffness of hysteretic and friction damping devices is permitted to be excluded from response spectrum analysis (RSA), provided that design forces in displacement-dependent damping devices, Q_{DSD}, are applied to the model as external loads (Section 18.7.4.5).
2. For velocity-dependent damping devices: Velocity-dependent damping devices that have a stiffness component (e.g., viscoelastic damping devices) shall be modeled with an effective stiffness corresponding to the amplitude and frequency of interest.

18.7.1.2 Seismic Force-Resisting System

18.7.1.2.1 Seismic Base Shear The seismic base shear, V, of the structure in a given direction shall be determined as the combination of modal components, V_m, subject to the limits of Equation (18.7-1):

Table 18.7-2. Force Coefficient,[a,b] C_{mFD}.

	$\mu \leq 1.0$[c]				
Effective Damping	$\alpha \leq 0.25$	$\alpha = 0.5$	$\alpha = 0.75$	$\alpha \geq 1.0$	$C_{mFD} = 1.0$

≥1.0	1.00	1.00	1.00	1.00

[a] Unless analysis or test data support other values, the force coefficient C_{mFV} for viscoelastic systems shall be taken as 1.0.
[b] Interpolation shall be used for intermediate values of velocity exponent, α.

$$V \ge V_{\min} \tag{18.7-1}$$

The seismic base shear, V, of the structure shall be determined by the square root of the sum of the squares method (SRSS) or complete quadratic combination of modal base shear components, V_m.

18.7.1.2.2 Modal Base Shear Modal base shear of the mth mode of vibration, V_m, of the structure in the direction of interest shall be determined in accordance with Equations (18.7-2a) and (18.7-2b):

$$V_m = C_{Sm}\overline{W}_m \tag{18.7-2a}$$

$$\overline{W}_m = \frac{\left(\sum_{n}^{i=1} w_i\phi_{im}\right)^2}{\sum_{n}^{i=1} w_i\phi_{im}^2} \tag{18.7-2b}$$

where

C_{Sm} = Seismic response coefficient of the mth mode of vibration of the structure in the direction of interest, as determined from Section 18.7.1.2.4 ($m = 1$) or Section 18.7.1.2.6 ($m > 1$);
$\overline{W}_m$ = Effective seismic weight of the mth mode of vibration of the structure; and
ϕ_{im} = Displacement amplitude at the ith level of the structure in the mth mode of vibration in the direction of interest, normalized to unity at the roof level.

18.7.1.2.3 Modal Participation Factor The modal participation factor of the mth mode of vibration, Γ_m, of the structure in the direction of interest shall be determined in accordance with Equation (18.7-3):

$$\Gamma_m = \frac{\overline{W}_m}{\sum_{n}^{i=1} w_i\phi_{im}} \tag{18.7-3}$$

18.7.1.2.4 Fundamental Mode Seismic Response Coefficient The fundamental mode ($m = 1$) seismic response coefficient, C_{S1}, in the direction of interest shall be determined in accordance with Equations (18.7-4) and (18.7-5):

For $T_{1D} < T_S$,

$$C_{S1} = \left(\frac{R}{C_d}\right)\frac{S_{DS}}{\Omega_0 B_{1D}} \tag{18.7-4}$$

For $T_{1D} \ge T_S$,

$$C_{S1} = \left(\frac{R}{C_d}\right)\frac{S_{D1}}{T_{1D}(\Omega_0 B_{1D})} \tag{18.7-5}$$

18.7.1.2.5 Effective Fundamental Mode Period Determination The effective fundamental mode ($m = 1$) period at the design earthquake ground motion, T_{1D}, and at the MCE_R ground motion, T_{1M}, shall be based on either explicit consideration of the postyield force deflection characteristics of the structure or determined in accordance with Equations (18.7-6) and (18.7-7):

$$T_{1D} = T_1\sqrt{\mu_D} \tag{18.7-6}$$

$$T_{1M} = T_1\sqrt{\mu_M} \tag{18.7-7}$$

18.7.1.2.6 Higher Mode Seismic Response Coefficient Higher mode ($m > 1$) seismic response coefficient, C_{Sm}, of the mth mode of vibration ($m > 1$) of the structure in the direction of interest shall be determined in accordance with Equations (18.7-8) and (18.7-9):

For $T_m < T_S$,

$$C_{Sm} = \left(\frac{R}{C_d}\right)\frac{S_{DS}}{\Omega_0 B_{mD}} \tag{18.7-8}$$

For $T_m \ge T_S$,

$$C_{Sm} = \left(\frac{R}{C_d}\right)\frac{S_{D1}}{T_m(\Omega_0 B_{mD})} \tag{18.7-9}$$

where T_m is the period(s), of the mth mode of vibration of the structure in the direction under consideration, and B_{mD} is the

@seismicisolation

numerical coefficient as set forth in Table 18.7-1 for effective damping equal to β_{mD} and period of the structure equal to T_m.

18.7.1.2.7 Design Lateral Force Design lateral force at level i caused by the mth mode of vibration, F_{im}, of the structure in the direction of interest shall be determined in accordance with Equation (18.7-10):

$$F_{im} = w_i \phi_{im} \frac{\Gamma_m}{W_m} V_m \tag{18.7-10}$$

Design forces in elements of the seismic force-resisting system shall be determined by the SRSS or complete quadratic combination of modal design forces.

18.7.1.3 Damping System Design forces in damping devices and other elements of the damping system shall be determined on the basis of the floor deflection, story drift, and story velocity response parameters described in the subsequent sections.

Displacements and velocities used to determine maximum forces in damping devices at each story shall account for the angle of orientation of each device from the horizontal and consider the effects of increased response caused by torsion required for design of the seismic force-resisting system.

Floor deflections at level i, δ_{iD} and δ_{iM}, story drifts, Δ_D and Δ_M, and story velocities, ∇_D and ∇_M, shall be calculated for both the design earthquake ground motions and the MCE_R ground motions, respectively, in accordance with this section.

18.7.1.3.1 Design Earthquake Floor Deflection The deflection of the structure caused by the design earthquake ground motions at level i in the mth mode of vibration, δ_{imD}, of the structure in the direction of interest shall be determined in accordance with Equation (18.7-11):

$$\delta_{imD} = D_{mD} \phi_{im} \tag{18.7-11}$$

The total design deflection at each floor of the structure shall be calculated by the SRSS or complete quadratic combination of modal design earthquake deflections.

18.7.1.3.2 Design Earthquake Roof Displacement Fundamental ($m = 1$) and higher mode ($m > 1$) roof displacements caused by the design earthquake ground motions, D_{1D} and D_{mD}, of the structure in the direction of interest shall be determined in accordance with Equations (18.7-12) and (18.7-13):

For $m = 1$,

$$D_{1D} = \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{DS} T_{1D}^2}{B_{1D}} \geq \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{DS} T_1^2}{B_{1E}}, \quad T_{1D} < T_S \tag{18.7-12a}$$

$$D_{1D} = \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{D1} T_{1D}}{B_{1D}} \geq \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{D1} T_1}{B_{1E}}, \quad T_{1D} \geq T_S \tag{18.7-12b}$$

For $m > 1$,

$$D_{mD} = \left(\frac{g}{4\pi^2}\right)\Gamma_m \frac{S_{D1} T_m}{B_{mD}} \leq \left(\frac{g}{4\pi^2}\right)\Gamma_m \frac{S_{DS} T_m^2}{B_{mD}} \tag{18.7-13}$$

18.7.1.3.3 Design Earthquake Story Drift Design story drift in the fundamental mode, Δ_{1D}, and higher modes, Δ_{mD} ($m > 1$), of the structure in the direction of interest shall be calculated in accordance with Section 12.8.6, using modal roof displacements of Section 18.7.1.3.2.

Total design story drift, ∇_D, shall be determined by the SRSS or complete quadratic combination of modal design earthquake drifts.

18.7.1.3.4 Design Earthquake Story Velocity Design story velocity in the fundamental mode, ∇_{1D}, and higher modes, ∇_{mD} ($m > 1$), of the structure in the direction of interest shall be calculated in accordance with Equations (18.7-14) and (18.7-15):

$$\text{For } m = 1, \quad \nabla_{1D} = 2\pi \frac{\Delta_{1D}}{T_{1D}} \tag{18.7-14}$$

$$\text{For } m > 1, \quad \nabla_{mD} = 2\pi \frac{\Delta_{mD}}{T_m} \tag{18.7-15}$$

Total design story velocity, ∇_D, shall be determined by the SRSS or complete quadratic combination of modal design velocities.

18.7.1.3.5 MCE_R Response Total modal maximum floor deflection at level i, MCE_R story drift values, and MCE_R story velocity values shall be based on Sections 18.7.1.3.1, 18.7.1.3.3, and 18.7.1.3.4, respectively, except design roof displacement shall be replaced by MCE_R roof displacement. MCE_R roof displacement of the structure in the direction of interest shall be calculated in accordance with Equations (18.7-16) and (18.7-17):

For $m = 1$,

$$D_{1M} = \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{MS} T_{1M}^2}{B_{1M}} \geq \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{MS} T_1^2}{B_{1E}}, \quad T_{1M} < T_S \tag{18.7-16a}$$

$$D_{1M} = \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{M1} T_{1M}}{B_{1M}} \geq \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{M1} T_1}{B_{1E}}, \quad T_{1M} \geq T_S \tag{18.7-16b}$$

For $m > 1$,

$$D_{mM} = \left(\frac{g}{4\pi^2}\right)\Gamma_m \frac{S_{M1} T_m}{B_{mM}} \leq \left(\frac{g}{4\pi^2}\right)\Gamma_m \frac{S_{MS} T_m^2}{B_{mM}} \tag{18.7-17}$$

where B_{mM} is a numerical coefficient as set forth in Table 18.7-1 for effective damping equal to β_{mM} and period of the structure equal to T_m.

18.7.2 Equivalent Lateral Force Procedure Where the equivalent lateral force procedure is used to design a structure with a damping system, the requirements of this section shall apply.

18.7.2.1 Modeling Elements of the seismic force-resisting system shall be modeled in a manner consistent with the requirements of Section 12.8. For purposes of analysis, the structure shall be considered to be fixed at the base.

Elements of the damping system shall be modeled as required to determine design forces transferred from the damping devices to both the ground and the seismic force-resisting system. The effective stiffness of velocity-dependent damping devices shall be modeled.

Damping devices need not be explicitly modeled provided that effective damping is calculated in accordance with the

@seismicisolation

procedures of Section 18.7.4 and used to modify response, as required in Sections 18.7.2.2 and 18.7.2.3.

The stiffness and damping properties of the damping devices used in the models shall be based on or verified by testing of the damping devices, as specified in Section 18.6.

18.7.2.2 Seismic Force-Resisting System

18.7.2.2.1 Seismic Base Shear. The seismic base shear, V, of the seismic force-resisting system in a given direction shall be determined as the combination of the two modal components, V_1 and V_R, in accordance with Equation (18.7-18):

$$V = \sqrt{V_1^2 + V_R^2} \geq V_{\min} \tag{18.7-18}$$

where

V_1 = Design value of the seismic base shear of the fundamental mode in a given direction of response, as determined in Section 18.7.2.2.2;

V_R = Design value of the seismic base shear of the residual mode in a given direction, as determined in Section 18.7.2.2.6; and

$V_{\min}$ = Minimum allowable value of base shear permitted for design of the seismic force-resisting system of the structure in the direction of interest, as determined in Section 18.2.1.1.

18.7.2.2.2 Fundamental Mode Base Shear The fundamental mode base shear, V_1, shall be determined in accordance with Equation (18.7-19):

$$V_1 = C_{S1}\overline{W}_1 \tag{18.7-19}$$

where C_{S1} is the fundamental mode seismic response coefficient, as determined in Section 18.7.2.2.4, and $\overline{W}_1$ is the effective fundamental mode seismic weight, including portions of the live load, as defined by Equation (18.7-2b) for $m = 1$.

18.7.2.2.3 Fundamental Mode Properties The fundamental mode shape, ϕ_{i1}, and participation factor, Γ_1, shall be determined by either dynamic analysis using the elastic structural properties and deformational characteristics of the resisting elements or using Equations (18.7-20) and (18.7-21):

$$\phi_{i1} = \frac{h_i}{h_n} \tag{18.7-20}$$

$$\Gamma_1 = \frac{\overline{W}_1}{\sum_{i=1}^{n} w_i \phi_{i1}} \tag{18.7-21}$$

where

h_i = The height above the base to level i;

h_n = The structural height as defined in Section 11.2; and

w_i = The portion of the total effective seismic weight, W, located at or assigned to level i.

The fundamental period, T_1, shall be determined either by dynamic analysis using the elastic structural properties and deformational characteristics of the resisting elements, or using Equation (18.7-22) as follows:

$$T_1 = 2\pi\sqrt{\frac{\sum_{i=1}^{n} w_i \delta_i^2}{g\sum_{i=1}^{n} f_i \delta_i}} \tag{18.7-22}$$

where f_i is the lateral force at level i of the structure distributed in accordance with Section 12.8.3, and δ_i is the elastic deflection at level i of the structure caused by applied lateral forces f_i.

18.7.2.2.4 Fundamental Mode Seismic Response Coefficient The fundamental mode seismic response coefficient, C_{S1}, shall be determined using Equations (18.7-23) or (18.7-24):

For $T_{1D} < T_S$,

$$C_{S1} = \left(\frac{R}{C_d}\right)\frac{S_{DS}}{\Omega_0 B_{1D}} \tag{18.7-23}$$

For $T_{1D} \geq T_S$,

$$C_{S1} = \left(\frac{R}{C_d}\right)\frac{S_{D1}}{T_{1D}(\Omega_0 B_{1D})} \tag{18.7-24}$$

where

S_{DS} = The design spectral response acceleration parameter in the short period range,

S_{D1} = The design spectral response acceleration parameter at a period of 1 s, and

B_{1D} = Numerical coefficient as set forth in Table 18.7-1 for effective damping equal to $\beta_{mD}(m = 1)$ and period of the structure equal to T_{1D}.

18.7.2.2.5 Effective Fundamental Mode Period Determination The effective fundamental mode period at the design earthquake, T_{1D}, and at the MCE$_R$, T_{1M}, shall be based on explicit consideration of the postyield force deflection characteristics of the structure or shall be calculated using Equations (18.7-25) and (18.7-26):

$$T_{1D} = T_1\sqrt{\mu_D} \tag{18.7-25}$$

$$T_{1M} = T_1\sqrt{\mu_M} \tag{18.7-26}$$

18.7.2.2.6 Residual Mode Base Shear Residual mode base shear, V_R, shall be determined in accordance with Equation (18.7-27):

$$V_R = C_{SR}\overline{W}_R \tag{18.7-27}$$

where C_{SR} is the residual mode seismic response coefficient as determined in Section 18.7.2.2.8, and $\overline{W}_R$ is the effective residual mode weight of the structure determined using Equation (18.7-30).

18.7.2.2.7 Residual Mode Properties Residual mode shape, ϕ_{iR}, participation factor, Γ_R, effective residual mode seismic weight of the structure, $\overline{W}_R$, and effective period, T_R, shall be determined using Equations (18.7-28) through (18.7-31):

$$\phi_{iR} = \frac{1 - \Gamma_1\phi_{i1}}{1 - \Gamma_1} \tag{18.7-28}$$

$$\Gamma_R = 1 - \Gamma_1 \tag{18.7-29}$$

$$\overline{W}_R = W - \overline{W}_1 \tag{18.7-30}$$

$$T_R = 0.4T_1 \tag{18.7-31}$$

@seismicisolation

18.7.2.2.8 Residual Mode Seismic Response Coefficient The residual mode seismic response coefficient, C_{SR}, shall be determined in accordance with Equation (18.7-32):

$$C_{SR} = \left(\frac{R}{C_d}\right)\frac{S_{DS}}{\Omega_0 B_R} \tag{18.7-32}$$

where B_R is a numerical coefficient as set forth in Table 18.7-1 for effective damping equal to β_R and period of the structure equal to T_R.

18.7.2.2.9 Design Lateral Force The design lateral force in elements of the seismic force-resisting system at level i caused by fundamental mode response, F_{i1}, and residual mode response, F_{iR}, of the structure in the direction of interest shall be determined in accordance with Equations (18.7-33) and (18.7-34):

$$F_{i1} = w_i \phi_{i1} \frac{\Gamma_1}{\overline{W}_1} V_1 \tag{18.7-33}$$

$$F_{iR} = w_i \phi_{iR} \frac{\Gamma_R}{\overline{W}_R} V_R \tag{18.7-34}$$

Design forces in elements of the seismic force-resisting system shall be determined by taking the SRSS of the forces caused by fundamental and residual modes.

18.7.2.3 Damping System Design forces in damping devices and other elements of the damping system shall be determined on the basis of the floor deflection, story drift, and story velocity response parameters described in the following sections.

Displacements and velocities used to determine maximum forces in damping devices at each story shall account for the angle of orientation of each device from the horizontal and consider the effects of increased response caused by torsion required for design of the seismic force-resisting system.

Floor deflections at level i, δ_{iD} and δ_{iM}, story drifts, Δ_D and Δ_M, and story velocities, ∇_D and ∇_M, shall be calculated for both the design earthquake ground motions and the MCE_R ground motions, respectively, in accordance with the following sections.

18.7.2.3.1 Design Earthquake Floor Deflection The total design deflection at each floor of the structure in the direction of interest shall be calculated as the SRSS of the fundamental and residual mode floor deflections. The fundamental and residual mode deflections caused by the design earthquake ground motions, δ_{i1D} and δ_{iRD}, at the center of rigidity of level i of the structure in the direction of interest shall be determined using Equations (18.7-35) and (18.7-36):

$$\delta_{i1D} = D_{1D}\phi_{i1} \tag{18.7-35}$$

$$\delta_{iRD} = D_{RD}\phi_{iR} \tag{18.7-36}$$

where D_{1D} is the fundamental mode design displacement at the center of rigidity of the roof level of the structure in the direction under consideration, Section 18.7.2.3.2, and D_{RD} is the residual mode design displacement at the center of rigidity of the roof level of the structure in the direction under consideration, Section 18.7.2.3.2.

18.7.2.3.2 Design Earthquake Roof Displacement Fundamental and residual mode displacements caused by the design earthquake ground motions, D_{1D} and D_{1R}, at the center of rigidity of the roof level of the structure in the direction of interest shall be determined using Equations (18.7-37) and (18.7-38):

$T_{1D} < T_S$

$$D_{1D} = \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{DS}T_{1D}^2}{B_{1D}} \geq \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{DS}T_1^2}{B_{1E}} \tag{18.7-37a}$$

$T_{1D} \geq T_S$

$$D_{1D} = \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{D1}T_{1D}}{B_{1D}} \geq \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{D1}T_1}{B_{1E}} \tag{18.7-37b}$$

$$D_{RD} = \left(\frac{g}{4\pi^2}\right)\Gamma_R \frac{S_{D1}T_R}{B_R} \leq \left(\frac{g}{4\pi^2}\right)\Gamma_R \frac{S_{DS}T_R^2}{B_R} \tag{18.7-38}$$

18.7.2.3.3 Design Earthquake Story Drift Design story drifts, Δ_D, in the direction of interest shall be calculated using Equation (18.7-39):

$$\Delta_D = \sqrt{\Delta_{1D}^2 + \Delta_{RD}^2} \tag{18.7-39}$$

where Δ_{1D} is the design story drift caused by the fundamental mode of vibration of the structure in the direction of interest and Δ_{RD} is the design story drift caused by the residual mode of vibration of the structure in the direction of interest.

Modal design story drifts, Δ_{1D} and Δ_{RD}, shall be determined as the difference of the deflections at the top and bottom of the story under consideration using the floor deflections of Section 18.7.2.3.1.

18.7.2.3.4 Design Earthquake Story Velocity Design story velocities, ∇_D, in the direction of interest shall be calculated in accordance with Equations (18.7-40) through (18.7-42):

$$\nabla_D = \sqrt{\nabla_{1D}^2 + \nabla_{RD}^2} \tag{18.7-40}$$

$$\nabla_{1D} = 2\pi\frac{\Delta_{1D}}{T_{1D}} \tag{18.7-41}$$

$$\nabla_{RD} = 2\pi\frac{\Delta_{RD}}{T_R} \tag{18.7-42}$$

where ∇_{1D} is the design story velocity caused by the fundamental mode of vibration of the structure in the direction of interest, and ∇_{RD} is the design story velocity caused by the residual mode of vibration of the structure in the direction of interest.

18.7.2.3.5 MCE_R Response Total modal MCE_R floor deflections at level i, maximum story drifts, and maximum story velocities shall be based on the equations in Sections 18.7.2.3.1, 18.7.2.3.3, and 18.7.2.3.4, respectively, except that design roof displacements shall be replaced by MCE_R roof displacements. MCE_R roof displacements shall be calculated in accordance with Equations (18.7-43) and (18.7-44):

$T_{1M} < T_S$

$$D_{1M} = \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{MS}T_{1M}^2}{B_{1M}} \geq \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{MS}T_1^2}{B_{1E}} \tag{18.7-43a}$$

$T_{1M} \geq T_S$

$$D_{1M} = \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{M1}T_{1M}}{B_{1M}} \geq \left(\frac{g}{4\pi^2}\right)\Gamma_1 \frac{S_{M1}T_1}{B_{1E}} \tag{18.7-43b}$$

$$D_{RM} = \left(\frac{g}{4\pi^2}\right)\Gamma_R \frac{S_{M1}T_R}{B_R} \leq \left(\frac{g}{4\pi^2}\right)\Gamma_R \frac{S_{MS}T_R^2}{B_R} \tag{18.7-44}$$

@seismicisolation
@seismicisolation

where

S_{M1} = MCE_R, 5% damped, spectral response acceleration parameter at a period of 1 s adjusted for site class effects, as defined in Section 11.4.4;

S_{MS} = MCE_R, 5% damped, spectral response acceleration parameter at short periods adjusted for site class effects, as defined in Section 11.4.4; and

B_{1M} = Numerical coefficient as set forth in Table 18.7-1 for effective damping equal to $\beta_{mM}(m=1)$ and period of structure equal to T_{1M}.

18.7.3 Damped Response Modification As required in Sections 18.7.1 and 18.7.2, response of the structure shall be modified for the effects of the damping system.

18.7.3.1 Damping Coefficient Where the period of the structure is greater than or equal to T_0, the damping coefficient shall be as prescribed in Table 18.7-1. Where the period of the structure is less than T_0, the damping coefficient shall be linearly interpolated between a value of 1.0 at a 0 s period for all values of effective damping and the value at period T_0, as indicated in Table 18.7-1.

18.7.3.2 Effective Damping The effective damping at the design displacement, β_{mD}, and at the MCE_R displacement, β_{mM}, of the mth mode of vibration of the structure in the direction under consideration shall be calculated using Equations (18.7-45) and (18.7-46):

$$\beta_{mD} = \beta_I + \beta_{Vm}\sqrt{\mu_D} + \beta_{HD} \tag{18.7-45}$$

$$\beta_{mM} = \beta_I + \beta_{Vm}\sqrt{\mu_M} + \beta_{HM} \tag{18.7-46}$$

where

β_{HD} = Component of effective damping of the structure in the direction of interest caused by postyield hysteretic behavior of the seismic force-resisting system and elements of the damping system at effective ductility demand, μ_D;

β_{HM} = Component of effective damping of the structure in the direction of interest caused by postyield hysteretic behavior of the seismic force-resisting system and elements of the damping system at effective ductility demand, μ_M;

β_I = Component of effective damping of the structure caused by the inherent dissipation of energy by elements of the structure, at or just below the effective yield displacement of the seismic force-resisting system;

β_{Vm} = Component of effective damping of the mth mode of vibration of the structure in the direction of interest caused by viscous dissipation of energy by the damping system, at or just below the effective yield displacement of the seismic force-resisting system;

μ_D = Effective ductility demand on the seismic force-resisting system in the direction of interest caused by the design earthquake ground motions; and

μ_M = Effective ductility demand on the seismic force-resisting system in the direction of interest caused by the MCE_R ground motions.

Unless analysis or test data support other values, the effective ductility demand of higher modes of vibration in the direction of interest shall be taken as 1.0.

18.7.3.2.1 Inherent Damping Inherent damping, β_I, shall be based on the material type, configuration, and behavior of the structure and nonstructural components responding dynamically at or just below yield of the seismic force-resisting system. Unless analysis or test data support other values, inherent damping shall be taken as not greater than 3% of critical for all modes of vibration.

18.7.3.2.2 Hysteretic Damping Hysteretic damping of the seismic force-resisting system and elements of the damping system shall be based either on test or analysis or shall be calculated using Equations (18.7-47) and (18.7-48):

$$\beta_{HD} = q_H(0.64 - \beta_I)\left(1 - \frac{1}{\mu_D}\right) \tag{18.7-47}$$

$$\beta_{HM} = q_H(0.64 - \beta_I)\left(1 - \frac{1}{\mu_M}\right) \tag{18.7-48}$$

where

q_H = Hysteresis loop adjustment factor, as defined in Section 18.7.3.2.2.1;

μ_D = Effective ductility demand on the seismic force-resisting system in the direction of interest caused by the design earthquake ground motions; and

μ_M = Effective ductility demand on the seismic force-resisting system in the direction of interest caused by the MCE_R ground motions.

Unless analysis or test data support other values, the hysteretic damping of higher modes of vibration in the direction of interest shall be taken as zero.

18.7.3.2.2.1 Hysteresis Loop Adjustment Factor. The calculation of hysteretic damping of the seismic force-resisting system and elements of the damping system shall consider pinching and other effects that reduce the area of the hysteresis loop during repeated cycles of earthquake demand. Unless analysis or test data support other values, the fraction of full hysteretic loop area of the seismic force-resisting system used for design shall be taken as equal to the factor, q_H, calculated using Equation (18.7-49):

$$q_H = 0.67\frac{T_S}{T_1} \tag{18.7-49}$$

where T_S is the period defined by the ratio, S_{D1}/S_{DS}, and T_1 is the period of the fundamental mode of vibration of the structure in the direction of interest.

The value of q_H shall not be taken as greater than 1.0 and need not be taken as less than 0.5.

18.7.3.2.3 Viscous Damping. Viscous damping of the mth mode of vibration of the structure, β_{Vm}, shall be calculated using Equations (18.7-50) and (18.7-51):

$$\beta_{Vm} = \frac{\sum_j W_{mj}}{4\pi W_m} \tag{18.7-50}$$

$$W_m = \frac{1}{2}\sum_j F_{im}\delta_{im} \tag{18.7-51}$$

where

W_{mj} = Work done by jth damping device in one complete cycle of dynamic response corresponding to the mth mode of vibration of the structure in the direction of interest at modal displacements, δ_{im};

W_m = Maximum strain energy in the mth mode of vibration of the structure in the direction of interest at modal displacements, δ_{im};

F_{im} = mth mode inertial force at level i; and

@seismicisolation

δ_{im} = Deflection of level i in the mth mode of vibration at the center of rigidity of the structure in the direction under consideration.

Viscous modal damping of displacement-dependent damping devices shall be based on a response amplitude equal to the effective yield displacement of the structure.

The calculation of the work done by individual damping devices shall consider orientation and participation of each device with respect to the mode of vibration of interest. The work done by individual damping devices shall be reduced as required to account for the flexibility of elements, including pins, bolts, gusset plates, brace extensions, and other components that connect damping devices to other elements of the structure.

18.7.3.3 Effective Ductility Demand The effective ductility demand on the seismic force-resisting system caused by the design earthquake ground motions, μ_D, and caused by the MCE_R ground motions, μ_M, shall be calculated using Equations (18.7-52) through (18.7-54):

$$\mu_D = \frac{D_{1D}}{D_Y} \geq 1.0 \tag{18.7-52}$$

$$\mu_M = \frac{D_{1M}}{D_Y} \geq 1.0 \tag{18.7-53}$$

$$D_Y = \left(\frac{g}{4\pi^2}\right)\left(\frac{\Omega_0 C_d}{R}\right)\Gamma_1 C_{S1} T_1^2 \tag{18.7-54}$$

where

D_{1D} = Fundamental mode design displacement at the center of rigidity of the roof level of the structure in the direction under consideration, Section 18.7.1.3.2 or 18.7.2.3.2;

D_{1M} = Fundamental mode maximum displacement at the center of rigidity of the roof level of the structure in the direction under consideration, Section 18.7.1.3.5 or 18.7.2.3.5;

D_Y = Displacement at the center of rigidity of the roof level of the structure at the effective yield point of the seismic force-resisting system;

R = Response modification coefficient from Table 12.2-1;

C_d = Deflection amplification factor from Table 12.2-1;

Ω_0 = Overstrength factor from Table 12.2-1;

Γ_1 = Participation factor of the fundamental mode of vibration of the structure in the direction of interest, Section 18.7.1.2.3 or 18.7.2.2.3 ($m = 1$);

C_{S1} = Seismic response coefficient of the fundamental mode of vibration of the structure in the direction of interest, Section 18.7.1.2.4 or 18.7.2.2.4 ($m = 1$); and

T_1 = Period of the fundamental mode of vibration of the structure in the direction of interest.

The design ductility demand, μ_D, shall not exceed the maximum value of effective ductility demand, μ_{max}, given in Section 18.7.3.4.

EXCEPTION: It is permitted to use nonlinear modeling, as described in Section 18.3, to develop a force-displacement (pushover) curve of the seismic force-resisting system. It is permitted to use this curve in lieu of the effective yield displacement, D_Y, of Equation (18.7-54) to calculate the effective ductility demand caused by the design earthquake ground motions, μ_D, and caused by the MCE_R ground motions, μ_M, in Equations (18.7-52) and (18.7-53), respectively. In this case, the value of (R/C_d) shall be taken as 1.0 in Equations (18.7-4), (18.7-5), (18.7-8), and (18.7-9).

18.7.3.4 Maximum Effective Ductility Demand For determination of the hysteresis loop adjustment factor, hysteretic damping, and other parameters, the maximum value of effective ductility demand, μ_{max}, shall be calculated using Equations (18.7-55) and (18.7-56):

For $T_{1D} \leq T_S$,

$$\mu_{max} = 0.5[(R/(\Omega_0 I_e))^2 + 1] \tag{18.7-55}$$

For $T_1 \geq T_S$,

$$\mu_{max} = R/(\Omega_0 I_e) \tag{18.7-56}$$

where I_e is the Importance Factor determined in accordance with Section 11.5.1, and T_{1D} is the effective period of the fundamental mode of vibration of the structure at the design displacement in the direction under consideration.

For $T_1 < T_S < T_{1D}$, μ_{max} shall be determined by linear interpolation between the values of Equations (18.7-55) and (18.7-56).

18.7.4 Seismic Load Conditions and Acceptance Criteria for RSA and ELF Procedures Design forces and displacements determined in accordance with the response spectrum procedure of Section 18.7.1, or the equivalent lateral force (ELF) procedure of Section 18.7.2, shall be checked using the strength design criteria of this standard and the seismic loading conditions of Section 18.7.4.3.

The seismic force-resisting system, damping system, seismic loading conditions, and acceptance criteria shall conform to the following subsections.

18.7.4.1 Seismic Force-Resisting System The seismic force-resisting system shall satisfy the requirements of Section 12.2.1 using seismic base shear and design forces determined in accordance with Section 18.7.1.2 or 18.7.2.2.

The design story drift, Δ_D, as determined in either Section 18.7.1.3.3 or 18.7.2.3.3, shall not exceed (R/C_d) times the allowable story drift, as obtained from Table 12.12-1, considering the effects of torsion, as required in Section 12.12.1.

18.7.4.2 Damping System The damping system shall satisfy the requirements of Section 12.2.1 for seismic design forces and seismic loading conditions determined in accordance with Section 18.7.4.3. Force-controlled elements of the damping system shall be designed for seismic forces that are increased by 20% from those corresponding to average MCE_R response.

18.7.4.3 Combination of Load Effects The effects on the damping system and its components caused by gravity loads and seismic forces shall be combined in accordance with Section 12.4, using the effect of horizontal seismic forces, Q_E, determined in accordance with Section 18.7.4.5. The redundancy factor, ρ, shall be taken equal to 1.0 in all cases, and the seismic load effect including overstrength of Section 12.4.3 need not apply to the design of the damping system.

18.7.4.4 Modal Damping System Design Forces Modal damping system design forces shall be calculated on the basis of the type of damping devices and the modal design story displacements and velocities determined in accordance with either Section 18.7.1.3 or 18.7.2.3.

Modal design story displacements and velocities shall be increased as required to envelop the total design story displacements and velocities determined in accordance with Section 18.3, where peak response is required to be confirmed by response history analysis.

@seismicisolation
@seismicisolation

For displacement-dependent damping devices: Design seismic force in displacement-dependent damping devices shall be based on the maximum force in the device at displacements up to, and including, the design story drift, Δ_D.

For velocity-dependent damping devices: Design seismic force in each mode of vibration in velocity-dependent damping devices shall be based on the maximum force in the device at velocities up to, and including, the design story velocity for the mode of interest.

Displacements and velocities used to determine design forces in damping devices at each story shall account for the angle of orientation of the damping device from the horizontal and consider the effects of increased floor response caused by torsional motions.

18.7.4.5 Seismic Load Conditions and Combination of Modal Responses Seismic design force, Q_E, in each element of the damping system shall be taken as the maximum force of the following three loading conditions:

1. Stage of maximum displacement: Seismic design force at the stage of maximum displacement shall be calculated in accordance with Equation (18.7-57):

$$Q_E = \Omega_0 \sqrt{\sum_m (Q_{mSFRS})^2} \pm Q_{DSD} \tag{18.7-57}$$

where Q_{mSFRS} is the force in an element of the damping system equal to the design seismic force of the mth mode of vibration of the structure in the direction of interest, and Q_{DSD} is the force in an element of the damping system required to resist design seismic forces of displacement-dependent damping devices.

Seismic forces in elements of the damping system, Q_{DSD}, shall be calculated by imposing design forces of displacement-dependent damping devices on the damping system as pseudostatic forces. Design seismic forces of displacement-dependent damping devices shall be applied in both positive and negative directions at peak displacement of the structure.

2. Stage of maximum velocity: Seismic design force at the stage of maximum velocity shall be calculated in accordance with Equation (18.7-58):

$$Q_E = \sqrt{\sum_m (Q_{mDSV})^2} \tag{18.7-58}$$

where Q_{mDSV} is the force in an element of the damping system required to resist design seismic forces of velocity-dependent damping devices caused by the mth mode of vibration of the structure in the direction of interest.

Modal seismic design forces in elements of the damping system, Q_{mDSV}, shall be calculated by imposing modal design forces of velocity-dependent devices on the nondeformed damping system as pseudostatic forces. Modal seismic design forces shall be applied in directions consistent with the deformed shape of the mode of interest. Horizontal restraint forces shall be applied at each floor level, i, of the nondeformed damping system concurrent with the design forces in velocity-dependent damping devices, such that the horizontal displacement at each level of the structure is zero. At each floor level, i, restraint forces shall be proportional to and applied at the location of each mass point.

3. Stage of maximum acceleration: Seismic design force at the stage of maximum acceleration shall be calculated in accordance with Equation (18.7-59):

$$Q_E = \sqrt{\sum_m (C_{mFD}\Omega_0 Q_{mSFRS} + \sum C_{mFV} Q_{mDSV})^2} \pm Q_{DSD} \tag{18.7-59}$$

The force coefficients, C_{mFD} and C_{mFV}, shall be determined from Tables 18.7-2 and 18.7-3, respectively, using values of effective damping determined in accordance with the following requirements:

For fundamental mode response ($m = 1$) in the direction of interest, the coefficients, C_{1FD} and C_{1FV}, shall be based on the velocity exponent, α, which relates device force to damping device velocity. The effective fundamental mode damping shall be taken as equal to the total effective damping of the fundamental mode less the hysteretic component of damping ($\beta_{1D} - \beta_{HD}$ or $\beta_{1M} - \beta_{HM}$) at the response level of interest ($\mu = \mu_D$ or $\mu = \mu_M$).

For higher mode ($m > 1$) or residual mode response in the direction of interest, the coefficients, C_{mFD} and C_{mFV}, shall be based on a value of α equal to 1.0. The effective modal damping shall be taken as equal to the total effective damping of the mode of interest (β_{mD} or β_{mM}). For determination of the coefficient C_{mFD}, the ductility demand shall be taken as equal to that of the fundamental mode ($\mu = \mu_D$ or $\mu = \mu_M$).

18.7.4.6 Inelastic Response Limits Elements of the damping system are permitted to exceed strength limits for design loads, provided it is shown by analysis or test that each of the following conditions are satisfied:

1. Inelastic response does not adversely affect damping system function.
2. Element forces, calculated in accordance with Section 18.7.4.5, using a value of Ω_0 taken as equal to 1.0, do not exceed the strength required to satisfy the load combinations of Section 12.4.

18.8 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

See Chapter 23 for the list of consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

CHAPTER 19
SOIL–STRUCTURE INTERACTION FOR SEISMIC DESIGN

19.1 GENERAL

19.1.1 Scope Determination of the design earthquake forces and he corresponding displacements of the structure is permitted to consider the effects of soil–structure interaction (SSI) in accordance with this section. If soil–structure interaction effects are considered, the analytical model of the structure shall directly incorporate horizontal, vertical, and rotational foundation and soil flexibility. For the purpose of this section, both upper and lower bound estimates for the foundation and soil stiffnesses per Section 12.13.3 shall be considered. The case that results in the smaller reduction, or greater amplification, in response parameters shall be used for design. SSI may be used in conjunction with the nonlinear response history procedure of Section 19.2.3 when the structure is located on Site Class C, D, E, or F. SSI base slab averaging and embedment effects may not be used in conjunction with the equivalent lateral procedure of Section 19.2.1 nor the linear dynamic procedure of Section 19.2.2.

If the provisions of this chapter are used, then Sections 12.8.1.3 and 12.13.4 shall not apply.

19.1.2 Definitions The following definitions apply to the provisions of Chapter 19 and are in addition to the definitions presented in Chapter 11:

BASE SLAB AVERAGING: Kinematic SSI of a shallow (nonembedded) foundation caused by wave incongruence over the base area.

FOUNDATION INPUT MOTION: Motion that effectively excites the structure and its foundation.

FREE-FIELD MOTION: Motion at ground surface in absence of structure and its foundation.

INERTIAL SSI: The dynamic interaction between the structure, its foundation, and the surrounding soil caused by the foundation input motion.

KINEMATIC SSI: The modification of free-field ground motion caused by nonvertical incident seismic waves and spatial incoherence; the modification yields the foundation input motion.

RADIATION DAMPING: The damping in the soil–structure system caused by the generation and propagation of waves away from the foundation, which are caused by dynamic displacements of the foundation relative to the free-field displacements.

SOIL DAMPING: The hysteretic (material) damping of the soil.

19.1.3 Symbols The following symbols apply only to the provisions of Chapter 19 as indicated and are in addition to the symbols presented in Chapter 11:

a_o = Dimensionless frequency [Equations (19.3-11) and (19.3-21)]

B = Half the smaller dimension of the base of the structure

B_{SSI} = Factor to adjust the design response spectrum and MCE_R response spectrum in accordance with Sections 11.4.6 and 11.4.7 or a site-specific response spectrum for damping ratios other than 0.05 [Equation (19.2-4)]

b_e = Effective foundation size [Equations (19.4-4) and (19.4-4SI)]

$\tilde{C}_s$ = Seismic response coefficient determined in accordance with Section 12.8.1.1, assuming a flexible structural base at the foundation–soil interface in accordance with Section 19.1

D_s = Depth of a soft layer overlaying a stiff layer [Equation (19.3-4)]

e = Foundation embedment depth

G_{rd} = Effective shear modulus used in determining radiation damping effects derived or approximated based on $G_{0,rd}$ and Table 19.3-2

$G_{0,rd}$ = Average shear modulus for the soils used in determining radiation damping effects computed using Equation (20.4-1), over a depth of B or r_f below the base of the structure at small strain levels

h^* = Effective structure height

K_{xx}, K_{rr} = Rotational foundation stiffness [Equations (19.3-9) and (19.3-19)]

K_y, K_r = Translational foundational stiffness [Equations (19.3-8) and (19.3-18)]

L = Half the larger dimension of the base of the structure

M^* = Effective modal mass for the fundamental mode of vibration in the direction under consideration

RRS_{bsa} = Site-specific response spectral modification factor for base-slab averaging [Equation (19.4-1)]

RRS_e = Site-specific response spectral modification factor for foundation embedment [Equation (19.4-5)]

r_f = Radius of the circular foundation

$\tilde{S}_a$ = Response spectral acceleration including the effects of SSI [Equations (19.2-5) through (19.2-8)]

T = Fundamental period of the structure determined in accordance with Section 12.8.2, based on a mathematical model with a fixed base condition. The upper bound limitation of C_uT_a on the fundamental period from Section 12.8.2 shall not apply, and the approximate structural period, T_a, shall not be used

$\tilde{T}$ = Fundamental period of the structure using a model with a flexible base in accordance with Section 19.1.1. The upper bound limitation of C_uT_a on the fundamental period from Section 12.8.2 shall not apply, and

@seismicisolation

the approximate structural period, T_a, shall not be used

$(\tilde{T}/T)_{\text{eff}}$ = Effective period lengthening that depends on expected ductility demand, μ [Equation (19.3-2)]

T_{xx}, T_{rr} = Fundamental translational period of SSI system [Equations (19.3-7) and (19.3-17)]

T_y, T_r = Fundamental translational period of SSI system [Equations (19.3-6) and (19.3-16)]

$\tilde{V}$ = Base shear adjusted for soil–structure interaction [Equation (19.2-1)]

$\tilde{V}_t$ = Base shear adjusted for soil–structure interaction determined through modal response spectrum analysis

$v_{s,e}$ = Average effective shear wave velocity for site soil conditions used in determining embedment effects, taken as average value of velocity over the embedment depth of the foundation determined using $v_{so,e}$ and Table 19.3-1 or a site-specific study and shall not be taken as less than 650 ft/s (200 m/s)

$v_{s,rd}$ = Average effective shear wave velocity used in determining radiation damping effects over a depth of B or r_f below the base of the structure, determined using $v_{so,rd}$ and Table 19.3-1 or a site-specific study

$v_{so,e}$ = Average low strain shear wave velocity used in determining embedment effects computed using Equation (20.4-1) over the embedment depth of the foundation

$v_{so,rd}$ = Average low strain shear wave velocity used in determining radiation damping effects computed using Equation 20.4-1 over a depth of B or r_f below the base of the structure

$\overline{W}$ = Weight caused by the modal mass in the fundamental mode, or alternatively, the effective seismic weight in accordance with Section 12.7.2

α = Coefficient that accounts for the reduction in base shear caused by foundation damping SSI

α_{xx}, α_{rr} = Dimensionless factor, function of dimensionless frequency, a_0 [Equations (19.3-14) and (19.3-24)]

β = Effective viscous damping ratio of the structure, taken as 5% unless otherwise justified by analysis

β_0 = Effective viscous damping ratio of the soil–structure system, based on Section 19.3.2 [Equation (19.3-1)]

β_f = Effective viscous damping ratio relating to foundation–soil interaction [Equation (19.3-3)]

β_{rd} = Radiation damping ratio determined in accordance with Section 19.3.3 or 19.3.4 [Equations (19.3-5) and (19.3-15)]

β_s, β_s' = Soil hysteretic damping ratio determined in accordance with Section 19.3.5

β_{xx}, β_{rr} = Rotational foundation damping coefficient [Equations (19.3-12) and (19.3-22)]

β_y, β_r = Translational foundation damping coefficient [Equations (19.3-10) and (19.3-20)]

γ = Average unit weight of the soils over a depth of B below the base of the structure

μ = Expected ductility demand

ν = Poisson's ratio; it is permitted to use 0.3 for sand and 0.45 for clay soils

Ψ = Dimensionless factor, function of Poisson's ratio [Equations (19.3-13) and (19.3-23)]

19.2 SSI ADJUSTED STRUCTURAL DEMANDS

19.2.1 Equivalent Lateral Force Procedure The inclusion of kinematic interaction effects, in accordance with Section 19.4 or other methods, is not permitted with the equivalent lateral force procedure. To account for the effects of SSI using a linear static procedure, the base shear, V, determined from Equation (12.8-1) is permitted to be modified as follows:

$$\tilde{V} = V - \Delta V \tag{19.2-1}$$

$$\Delta V = \left(C_s - \frac{\tilde{C}_s}{B_{\text{SSI}}}\right)\bar{W} \le 0.3\ V \tag{19.2-2}$$

$$B_{\text{SSI}} = 4/[5.6 - \ln(100\beta_0)] \le \begin{cases} 1.4 & \text{for } R \le 3 \\ 1.7 - \frac{R}{10} & \text{for } 3 < R < 6 \\ 1.1 & \text{for } R \ge 6 \end{cases} \tag{19.2-3}$$

where

$\tilde{V}$ = Base shear adjusted for SSI;

V = Fixed-base structure base shear computed in accordance with Section 12.8.1;

R = Response modification factor in Table 12.2-1;

Table 19.3-1. Effective Shear Wave Velocity Ratio $\left(\frac{v_{s,rd}}{v_{so,rd}} \text{ or } \frac{v_{s,e}}{v_{so,e}}\right)$.

Site Class	Effective Peak Acceleration, $S_{DS}/2.5$[a,c]			
	$S_{DS}/2.5 = 0$	$S_{DS}/2.5 = 0.1$	$S_{DS}/2.5 = 0.4$	$S_{DS}/2.5 \ge 0.8$
A	1.00	1.00	1.00	1.00
B	1.00	1.00	0.97	0.95
BC	1.00	0.98	0.92	0.86
C	1.00	0.97	0.87	0.77
CD	1.00	0.96	0.79	0.50
D	1.00	0.95	0.71	0.32
DE	1.00	0.86	0.40	0.18
E	1.00	0.77	0.22	[b]
F	[b]	[b]	[b]	[b]

[a] Use straight-line interpolation for intermediate values of $S_{DS}/2.5$.

[b] Site-specific geotechnical investigation and dynamic site response analyses shall be performed.

[c] It is permitted to apply this table to the MCE_R response spectrum, determined according to Section 11.4.7, the $S_{DS}/2.5$ headers shall be replaced by $S_{MS}/2.5$; to apply the table to the site-specific MCE_R response spectrum, determined according to Chapter 21, the $S_{DS}/2.5$ headers shall be replaced by the MCE_R response spectral acceleration at 0.01 s natural period.

@seismicisolation

C_s = Seismic response coefficient determined in accordance with Section 12.8.1.1, assuming a fixed structural base at the foundation–soil interface;

$\tilde{C}_s$ = Seismic response coefficient determined in accordance with Section 12.8.1.1, assuming flexibility of the structural base at the foundation–soil interface in accordance with Section 19.1.1, using $\tilde{T}$ as the fundamental period of the structure in lieu of the fundamental period of the structure, T, as determined by Section 12.8.2;

$\overline{W}$ = Weight caused by the effective modal mass in the fundamental mode, alternatively taken as the effective seismic weight in accordance with Section 12.7.2; and

β_0 = Effective viscous damping ratio of the soil–structure system, in accordance with Section 19.3.2.

19.2.2 Linear Dynamic Analysis The inclusion of kinematic interaction effects, in accordance with Section 19.4 or other methods, is not permitted with the linear dynamic procedure. To account for the effects of SSI, a linear dynamic analysis is permitted to be performed in accordance with Section 12.9, using either the SSI modified design response spectrum and MCE_R response spectrum in accordance with Sections 11.4.6 and 11.4.7 or SSI modified site-specific response spectrum, per Section 19.2.2.1 or an SSI modified site-specific response spectrum in accordance with Section 19.2.2.2 for spectral response acceleration, $\tilde{S}_a$, versus structural period, T. The resulting response spectral acceleration shall be divided by R/I_e, where I_e is prescribed in Section 11.5.1. The mathematical model used for the linear dynamic analysis shall include flexibility of the foundation and underlying soil in accordance with Section 19.1.1.

Scaling of the lateral forces from the modal response analysis shall be in accordance with Section 12.9.1.4 with calculated base shear, V, replaced with SSI adjusted base shear, $\tilde{V}$, determined in accordance with Equation (19.2-1) and the modal base shear, V_t, replaced by the modal base shear calculated with the effects of SSI, $\tilde{V}_t$.

The modal base shear calculated with the effects of SSI, $\tilde{V}_t$, shall not be less than $0.7V$.

19.2.2.1 SSI Modified General Design Response Spectrum The general design response spectrum, which includes the effects of SSI to be used with the modal analysis procedure in Section 19.2.2, shall be developed as follows:

$$\tilde{S}_a = \left[\left(\frac{5}{B_{SSI}} - 2\right) \times \frac{T}{T_S} + 0.4\right] \times S_{DS} \qquad (19.2\text{-}4)$$

For $0 < T < T_0$, and

$$\tilde{S}_a = S_{DS}/B_{SSI} \quad \text{for } T_0 \le T \le T_S, \quad \text{and}$$

$$\tilde{S}_a = S_{D1}/(B_{SSI}T), \quad \text{for } T_S < T \le T_L, \quad \text{and}$$

$$\tilde{S}_a = S_{D1}T_L/(B_{SSI}T^2), \quad \text{for } T > T_L$$

where S_{DS} and S_{D1} are defined in Section 11.4.5; T_S, T_0, and T_L are as defined in Section 11.4.6; T is the period at the response spectrum ordinate; and B_{SSI} is defined in Equation (19.2-3).

19.2.2.2 SSI Site-Specific Response Spectrum A site-specific response spectrum that incorporates modifications caused by SSI is permitted to be developed in accordance with the requirements of Chapter 21. The spectrum is permitted to be adjusted for the effective viscous damping ratio of β_0, of the soil–structure system, as defined in Section 19.3.2, in the development of the site-specific spectrum.

19.2.3 Nonlinear Response History Procedure It is permitted to account for the effects of SSI using a nonlinear response history analysis performed in accordance with Chapter 16 using acceleration histories scaled to a site-specific response spectrum modified for kinematic interaction, in accordance with Section 19.4 or other approved methods. The mathematical model used for the analysis shall include foundation and soil flexibility, per Section 19.1.1, and shall explicitly incorporate the effects of foundation damping, per Section 19.3 or by other approved methods. Kinematic interaction effects, per Section 19.4, are permitted to be included in the determination of the site-specific response spectrum.

The site-specific response spectrum shall be developed, per the requirements of Chapter 21, with the following additional requirements:

1. The spectrum is permitted to be adjusted for kinematic SSI effects by multiplying the spectral acceleration ordinate at each period by the corresponding response spectrum ratios for either base slab averaging or embedment, or both base slab averaging and embedment ($RRS_{bsa} \times RRS_e$) per Section 19.4, or by directly incorporating one or both of these effects into the development of the spectrum.
2. For structures embedded in the ground, the site-specific response spectrum is permitted to be developed at the depth of the embedded base level in lieu of at grade. For this case, the response spectrum ratio for embedment effects (RRS_e) shall be taken as 1.0.
3. The site-specific response spectrum modified for kinematic interaction shall not be taken as less than 80% of S_a as determined from a site-specific response spectrum in accordance with Section 21.3.
4. The site-specific response spectrum modified for kinematic interaction shall not be taken as less than 70% of S_a, as determined from the design response spectrum and MCE_R response spectrum in accordance with Sections 11.4.6 and 11.4.7.

If the acceleration histories are scaled to a site-specific spectrum modified for kinematic soil–structure interaction it is permitted to include kinematic soil–structure interaction in the equivalent lateral force procedure or the linear dynamic procedure conducted per Section 16.1.2 using the site-specific response spectrum modified for kinematic soil–structure interaction, subject to the limitations herein. Where foundation damping is included in the nonlinear model, the equivalent lateral force procedure or the linear dynamic procedure, in conjunction with Section 16.1.2, shall be based on the provisions of 19.2.1 or 19.2.2, respectively.

19.3 FOUNDATION DAMPING EFFECTS

19.3.1 Foundation Damping Requirements Foundation damping effects are permitted to be considered through direct incorporation of soil hysteretic damping and radiation damping in the mathematical model of the structure. The use of the procedures in this section are permitted in conjunction with the equivalent lateral procedure modifications of Section 19.2.1 or the linear dynamic procedure modifications of Section 19.2.2, unless any of the following conditions occur:

1. A foundation system consisting of discrete footings that are not interconnected and that are spaced less than the larger

@seismicisolation

dimension of the supported lateral force-resisting element in the direction under consideration.

2. A foundation system consisting of, or including, deep foundations such as piles or piers.
3. A foundation system consisting of structural mats interconnected by concrete slabs that are characterized as flexible in accordance with Section 12.3.1.3 or that are not continuously connected to grade beams or other foundation elements.

19.3.2 Effective Damping Ratio The effects of foundation damping shall be represented by the effective damping ratio of the soil–structure system, β_0, determined in accordance with Equation (19.3-1):

$$\beta_0 = \beta_f + \frac{\beta}{(\widetilde{T}/T)^2_{\text{eff}}} \le 0.20 \tag{19.3-1}$$

where

β_f = Effective viscous damping ratio relating to foundation–soil interaction;
β = Effective viscous damping ratio of the structure, taken as 5%, unless otherwise justified by analysis; and
$(\widetilde{T}/T)_{\text{eff}}$ = Effective period lengthening ratio defined in Equation (19.3-2).

The effective period lengthening ratio shall be determined in accordance with Equation (19.3-2):

$$\left(\frac{\widetilde{T}}{T}\right)_{\text{eff}} = \left\{1 + \frac{1}{\mu}\left[\left(\frac{\widetilde{T}}{T}\right)^2 - 1\right]\right\}^{0.5} \tag{19.3-2}$$

where μ is the expected ductility demand. For equivalent lateral force or modal response spectrum analysis procedures, μ is the maximum base shear divided by the elastic base shear capacity; alternately, μ is permitted to be taken as R/Ω_0, where R and Ω_0 are per Table 12.2-1. For the response history analysis procedures, μ is the maximum displacement divided by the yield displacement of the structure measured at the highest point above grade.

The foundation damping ratio caused by soil hysteretic damping and radiation damping, β_f, is permitted to be determined in accordance with Equation (19.3-3) or by other approved methods.

$$\beta_f = \left[\frac{(\widetilde{T}/T)^2 - 1}{(\widetilde{T}/T)^2}\right]\beta_s + \beta_{rd} \tag{19.3-3}$$

where β_s is the soil hysteretic damping ratio, determined in accordance with Section 19.3.5, and β_{rd} is the radiation damping ratio, determined in accordance with Section 19.3.3 or 19.3.4.

If a site more than a depth B or R below the base of the building consists of a relatively uniform layer of depth, D_s, overlaying a very stiff layer with a shear wave velocity more than twice that of the surface layer and $4D_s/v_s\widetilde{T} < 1$, then the damping values, β_r, in Equation (19.3-3) shall be replaced by β_s', per Equation (19.3-4):

$$\beta_s' = \left(\frac{4D_s}{v_s\widetilde{T}}\right)^4 \beta_s \tag{19.3-4}$$

19.3.3 Radiation Damping for Rectangular Foundations The effects of radiation damping for structures with a rectangular foundation plan shall be represented by the effective damping ratio of the soil–structure system, β_{rd}, determined in accordance with Equation (19.3-15):

$$a_0 = \frac{2\pi B}{\widetilde{T}v_{s,rd}} \tag{19.3-5}$$

$$\psi = \sqrt{\frac{2(1-\nu)}{(1-2\nu)}} \le 2.5 \tag{19.3-6}$$

$$\alpha_{xx} = 1.0 - \left[\frac{(0.55 + 0.01\sqrt{(L/B)-1})a_0^2}{(2.4 - \frac{0.4}{(L/B)^3}) + a_0^2}\right] \tag{19.3-7}$$

$$G_{0,rd} = \gamma v_{so,rd}^2/g \tag{19.3-8}$$

$$K_y = \frac{G_{rd}B}{2-\nu}\left[6.8\left(\frac{L}{B}\right)^{0.65} + 0.8\left(\frac{L}{B}\right) + 1.6\right] \tag{19.3-9}$$

$$K_{xx} = \frac{G_{rd}B^3}{1-\nu}\left[3.2\left(\frac{L}{B}\right) + 0.8\right] \tag{19.3-10}$$

$$\beta_y = \left[\frac{4(L/B)}{(K_y/G_{rd}B)}\right]\left[\frac{a_0}{2}\right] \tag{19.3-11}$$

$$\beta_{xx} = \left[\frac{(4\psi/3)(L/B)a_0^2}{(\frac{K_{xx}}{G_{rd}B^3})[(2.2 - \frac{0.4}{(L/B)^3}) + a_0^2]}\right]\left[\frac{a_0}{2\alpha_{xx}}\right] \tag{19.3-12}$$

$$T_y = 2\pi\sqrt{\frac{M^*}{K_y}} \tag{19.3-13}$$

$$T_{xx} = 2\pi\sqrt{\frac{M^*(h^*)^2}{\alpha_{xx}K_{xx}}} \tag{19.3-14}$$

$$\beta_{rd} = \frac{1}{(\widetilde{T}/T_y)^2}\beta_y + \frac{1}{(\widetilde{T}/T_{xx})^2}\beta_{xx} \tag{19.3-15}$$

where

M^* = Effective modal mass for the fundamental mode of vibration in the direction under consideration;
h^* = Effective structure height taken as the vertical distance from the foundation to the centroid of the first mode shape for multistory structures. Alternatively, h^* is permitted to be approximated as 70% of the total structure height for multistory structures or as the full height of the structure for one-story structures;
L = Half the larger dimension of the base of the structure;
B = Half the smaller dimension of the base of the structure;
$v_{s,rd}$ = Average effective shear wave velocity over a depth of B below the base of the structure determined using $v_{so,rd}$ and Table 19.3-1 or a site-specific study;
$v_{so,rd}$ = Average low strain shear wave velocity computed using Equation (20.4-1) over a depth of B below the base of the structure;
G_{rd} = Effective shear modulus derived or approximated based on $G_{0,rd}$ and Table 19.3-2;
$G_{0,rd}$ = Average shear modulus for the soils computed using Equation (20.4-1) over a depth B below the base of the structure at small strain levels;

@seismicisolation

Table 19.3-2. Effective Shear Modulus Ratio ($G_{rd}/G_{0,rd}$).

Site Class	Effective Peak Acceleration, $S_{DS}/2.5$[a,c]			
	$S_{DS}/2.5 = 0$	$S_{DS}/2.5 = 0.1$	$S_{DS}/2.5 = 0.4$	$S_{DS}/2.5 \geq 0.8$
A	1.00	1.00	1.00	1.00
B	1.00	1.00	0.95	0.90
BC	1.00	0.97	0.84	0.73
C	1.00	0.95	0.75	0.60
CD	1.00	0.92	0.62	0.25
D	1.00	0.90	0.50	0.10
DE	1.00	0.73	0.16	0.03
E	1.00	0.60	0.05	[b]
F	[b]	[b]	[b]	[b]

[a] Use straight-line interpolation for intermediate values of $S_{DS}/2.5$.
[b] Site-specific geotechnical investigation and dynamic site response analyses shall be performed.
[c] It is permitted to apply this table to the MCE_R response spectrum, determined according to Section 11.4.7, the $S_{DS}/2.5$ headers shall be replaced by $S_{MS}/2.5$; to apply the table to the site-specific MCE_R response spectrum determined according to Chapter 21, the $S_{DS}/2.5$ headers shall be replaced by the MCE_R response spectral acceleration at 0.01 s natural period.

γ = Average unit weight of the soils over a depth of B below the base of the structure; and
ν = Poisson's ratio; it is permitted to use 0.3 for sandy and 0.45 for clayey soils.

19.3.4 Radiation Damping for Circular Foundations The effects of radiation damping for structures with a circular foundation plan shall be represented by the effective damping ratio of the soil–structure system, β_{rd}, [Equation (19.3-25)] determined in accordance with Equation (19.3-15):

$$a_0 = \left[\frac{2\pi r_f}{\widetilde{T} v_{s,rd}}\right] \tag{19.3-16}$$

$$\psi = \sqrt{\frac{2(1-\nu)}{(1-2\nu)}} \leq 2.5 \tag{19.3-17}$$

$$\alpha_{rr} = 1.0 - \left[\frac{0.35 a_0^2}{1.0 + a_0^2}\right] \tag{19.3-18}$$

$$K_r = \frac{8 G_{rd} r_f}{2-\nu} \tag{19.3-19}$$

$$K_{rr} = \frac{8 G_{rd} {r_f}^3}{3(1-\nu)} \tag{19.3-20}$$

$$\beta_r = \left[\frac{\pi}{(K_r/G_{rd} r_f)}\right]\left[\frac{a_0}{2}\right] \tag{19.3-21}$$

$$\beta_{rr} = \left[\frac{(\pi\psi/4) a_0^2}{(K_{rr}/G_{rd} r_f^3)[2 + a_0^2]}\right]\left[\frac{a_0}{2\alpha_{rr}}\right] \tag{19.3-22}$$

$$T_r = 2\pi\sqrt{\frac{M^*}{K_r}} \tag{19.3-23}$$

$$T_{rr} = 2\pi\sqrt{\frac{M^* (h^*)^2}{\alpha_{rr} K_{rr}}} \tag{19.3-24}$$

$$\beta_{rd} = \frac{1}{(\widetilde{T}/T_r)^2}\beta_r + \frac{1}{(\widetilde{T}/T_{rr})^2}\beta_{rr} \tag{19.3-25}$$

where

r_f = Radius of the circular foundation;
$v_{s,rd}$ = The average effective shear wave velocity used in determining radiation damping effects over a depth of r_f below the base of the structure determined using $v_{so,rd}$ and Table 19.3-1 or a site-specific study;
$v_{so,rd}$ = The average low strain shear wave velocity used in determining radiation damping effects computed using Equation (20.4-1) over a depth of r_f below the base of the structure;
γ = The average unit weight of the soils over a depth of r_f below the base of the structure;
G_{rd} = Effective shear modulus used in determining radiation damping effects derived or approximated based on $G_{0,rd}$ and Table 19.3-2; and
$G_{0,rd} = \gamma v_{so,rd}^2/g$, the average shear modulus for the soils used in determining radiation damping effects computed using Equation (20.4-1) over a depth of r_f below the base of the structure at small strain levels.

19.3.5 Soil Damping The effects of soil hysteretic damping shall be represented by the effective soil hysteretic damping ratio, β_s, determined based on a site-specific study. Alternatively, it is permitted to determine β_s in accordance with Table 19.3-3.

19.4 BASE SLAB AVERAGING AND EMBEDMENT (KINEMATIC) SSI EFFECTS

Kinematic SSI effects are permitted to be represented by response spectral modification factors RRS_{bsa} for base slab averaging and RRS_e for embedment, which are multiplied by the spectral acceleration ordinates of the response spectrum at each period. The modification factors are calculated in accordance with Sections 19.4.1 and 19.4.2. Modifications of the response spectrum for kinematic SSI effects are permitted only for use with the nonlinear response history analysis provisions of Chapter 16, using the site-specific response spectrum developed

@seismicisolation

Table 19.3-3. Soil Hysteretic Damping Ratio, β_s.

Site Class	Effective Peak Acceleration, $S_{DS}/2.5$[a]			
	$S_{DS}/2.5 = 0$	$S_{DS}/2.5 = 0.1$	$S_{DS}/2.5 = 0.4$	$S_{DS}/2.5 \geq 0.8$
C	0.01	0.01	0.03	0.05
CD	0.01	0.01	0.05	0.09
D	0.01	0.02	0.07	0.15
DE	0.01	0.03	0.12	0.20
E	0.01	0.05	0.20	[b]
F	[b]	[b]	[b]	[b]

[a] Use straight-line interpolation for intermediate values of $S_{DS}/2.5$.
[b] Site-specific geotechnical investigation and dynamic site response analyses shall be performed.

in accordance with Chapter 21 and subject to the limitations in Sections 19.2.3, 19.4.1, and 19.4.2.

The product of $RRS_{\text{bsa}} \times RRS_e$ shall not be less than 0.7.

19.4.1 Base Slab Averaging Consideration of the effects of base slab averaging through the development of site-specific transfer functions that represent the kinematic SSI effects expected at the site for a given foundation configuration is permitted.

Alternatively, modifications for base slab averaging using the procedures of this section are permitted for the following cases:

1. All structures located on Site Class C, CD, D, DE, or E; and
2. Structures that have structural mats or foundation elements interconnected with concrete slabs or that are continuously connected with grade beams or other foundation elements of sufficient lateral stiffness, so as not to be characterized as flexible under the requirements of Section 12.3.1.3.

The *modification* factor for base slab averaging, RRS_{bsa}, shall be determined using Equation (19.4-1) for each period required for analysis.

$$RRS_{\text{bsa}} = 0.25 + 0.75 \times \left\{ \frac{1}{b_0^2} \left[1 - (\exp(-2b_0^2)) \times B_{\text{bsa}} \right] \right\}^{1/2} \tag{19.4-1}$$

where

$$B_{\text{bsa}} = \begin{cases} 1 + b_0^2 + b_0^4 + \frac{b_0^6}{2} + \frac{b_0^8}{4} + \frac{b_0^{10}}{12} & b_0 \leq 1 \\ [\exp(2b_0^2)] \times \left[\frac{1}{\sqrt{\pi} b_0} \left(1 - \frac{1}{16 b_0^2} \right) \right] & b_0 > 1 \end{cases} \tag{19.4-2}$$

$$b_0 = 0.00071 \times \left(\frac{b_e}{T} \right) \tag{19.4-3}$$

where b_e is the effective foundation size (ft),

$$b_0 = 0.0023 \times \left(\frac{b_e}{T} \right) \tag{19.4-3.SI}$$

where b_e is the effective foundation size (m),

$$b_e = \sqrt{A_{\text{base}}} \leq 260\,\text{ft} \tag{19.4-4}$$

$$b_e = \sqrt{A_{\text{base}}} \leq 80\,\text{m} \tag{19.4-4.SI}$$

T is the response spectra ordinate period, which shall not be taken as less than 0.20 s when used in Equations (19.4-3) or (19.4-3.SI); and A_{base} is the area of the base of the structure [ft^2 (m^2)].

19.4.2 Embedment The response spectrum shall be developed based on a site-specific study at the depth of the base of the structure. Alternatively, modifications for embedment are permitted using the procedures of this section.

The modification factor for embedment, RRS_e, shall be determined using Equation (19.4-5) for each period required for analysis.

$$RRS_e = 0.25 + 0.75 \times \cos\left(\frac{2\pi e}{T v_{s,e}} \right) \tag{19.4-5}$$

where

e = Foundation embedment depth [ft (m)], not greater than 20 ft (6.1 m) and not greater than the bottom of the base slab diaphragm; a minimum of 75% of the foundation footprint shall be present at the embedment depth, and the foundation embedment for structures located on sloping sites shall be the shallowest embedment;

$v_{s,e}$ = The average effective shear wave velocity for site soil conditions used in determining embedment effects, taken as average value of velocity over the embedment depth of the foundation determined using $v_{so,e}$ and Table 19.3-1 or a site-specific study and shall not be taken as less than 650 ft/s (200 m/s);

$v_{so,e}$ = The average low strain shear wave velocity used in determining embedment effects computed using Equation (20.4-1) over the embedment depth of the foundation; and

T = Response spectra ordinate period, which shall not be taken as less than 0.20 s when used in Equation (19.4-5).

19.5 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

See Chapter 23 for the list of consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

@seismicisolation

CHAPTER 20
SITE CLASSIFICATION PROCEDURE FOR SEISMIC DESIGN

20.1 SITE CLASSIFICATION

The site soil shall be classified in accordance with Table 20.2-1 and Section 20.2 based on the average shear wave velocity parameter, $\bar{v}_s$, which is derived from the measured shear wave velocity profile from the ground surface to a depth of 100 ft (30 m). Where shear wave velocity is not measured, appropriate generalized correlations between shear wave velocity and standard penetration test (SPT) blow counts, Cone Penetration Test (CPT) tip resistance, shear strength, or other geotechnical parameters shall be used to obtain an estimated shear wave velocity profile, as described in Section 20.3. Where site-specific data (measured shear wave velocities or other geotechnical data that can be used to estimate shear wave velocity) are available only to a maximum depth less than 100 ft (30 m), $\bar{v}_s$ shall be estimated as described in Section 20.3. Where the soil properties are not known in sufficient detail to determine the site class, the most critical site conditions of Site Class C, Site Class CD and Site Class D, as defined in Section 11.4.2, shall be used unless the Authority Having Jurisdiction or geotechnical data determine that Site Class DE, E, or F soils are present at the site. Site Classes A and B shall not be assigned to a site if there is more than 10 ft (3.1 m) of soil between the rock surface and the bottom of the spread footing or mat foundation.

20.2 SITE CLASS DEFINITIONS

Site class types shall be assigned in accordance with the definitions provided in Table 20.2-1 and this section.

20.2.1 Site Class F Where any of the following conditions is satisfied, the site shall be classified as Site Class F and a site response analysis, in accordance with Section 21.1, shall be performed:

1. Soil profile that includes soils vulnerable to potential failure or collapse under seismic loading, such as liquefiable soils, quick and highly sensitive clays, and collapsible weakly cemented soils.

   EXCEPTION: For structures that have fundamental periods of vibration equal to, or less than, 0.5 s, site response analysis is not required to determine spectral accelerations for liquefiable soils. Rather, for the purpose of determining spectral accelerations only, a site class is permitted to be determined in accordance with Section 20.2 and the corresponding response spectrum determined from Section 11.4.
2. Soil profile includes peats and/or highly organic clays [$H > 10$ ft ($H > 3$ m)] where H = thickness of soil.
3. Soil profile includes very high plasticity clays [$H > 25$ ft ($H > 7.6$ m) with $PI > 75$] in a soil profile that would otherwise be classified as Site Class CD, D, DE, or E.

   EXCEPTION: Site response analysis is not required for this clay category for Seismic Design Category A and Seismic Design Category B, where the seismic design category is based on the values S_{DS} and S_{D1}.
4. Soil profile includes very thick soft/medium stiff clays [$H > 120$ ft ($H > 37$ m)] with $s_u < 1,000$ psf ($s_u < 50$ kPa).

   EXCEPTION: Site response analysis is not required for this clay category for Seismic Design Category A and Seismic Design Category B, where the seismic design category is based on the values S_{DS} and S_{D1}.

20.2.2 Soft Clay Site Class E Where a site does not qualify under the criteria for Site Class F and there is a total thickness of soft clay greater than 10 ft (3 m), where a soft clay layer is defined by $s_u < 500$ psf ($s_u < 25$ kPa), $w \geq 40\%$, and $PI > 20$, it shall be classified as Site Class E. This classification is made regardless of $\bar{v}_s$, as computed in Section 20.4.

20.2.3 Site Classes C, CD, D, DE, and E The assignment of Site Class C, CD, D, DE, and E soils shall be made based on the average shear wave velocity, $\bar{v}_s$, which is derived from the site shear wave velocity profile from the ground surface to a depth of 100 ft (30 m), as described in Section 20.4.

20.2.4 Site Classes B and BC (Medium Hard and Soft Rock) Site Class B can only be assigned to a site on the basis of shear wave velocity measured on site. If shear wave velocity data are not available and the site condition is estimated by a geotechnical engineer, engineering geologist, or seismologist as Site Class B or BC on the basis of site geology, consisting of competent rock with moderate fracturing and weathering, the site shall be classified as Site Class BC. Softer and more highly fractured and weathered rock shall either be measured on site for shear wave velocity or classified as Site Class C.

20.2.5 Site Class A (Hard Rock) The hard rock, Site Class A, category shall be supported by shear wave velocity measurement, either on site or on profiles of the same rock type in the same formation with an equal or greater degree of weathering and fracturing. Where hard rock conditions are known to be continuous to a depth of 100 ft (30 m), surficial shear wave velocity measurements to maximum depths less than 100 ft are permitted to be extrapolated to assess $\bar{v}_s$.

@seismicisolation
@seismicisolation

Table 20.2-1. Site Classification.

Site Class	$\bar{v}_s$ Calculated Using Measured or Estimated Shear Wave Velocity Profile (ft/s)
A. Hard rock	>5,000
B. Medium hard rock	>3,000 to 5,000
BC. Soft rock	>2,100 to 3,000
C. Very dense sand or hard clay	>1,450 to 2,100
CD. Dense sand or very stiff clay	>1,000 to 1,450
D. Medium dense sand or stiff clay	>700 to 1,000
DE. Loose sand or medium stiff clay	>500 to 700
E. Very loose sand or soft clay	≥500
F. Soils requiring site response analysis in accordance with Section 21.1	See Section 20.2.1

Note: For SI: 1 ft = 0.3048 m; 1 ft/s = 0.3048 m/s.

20.3 ESTIMATION OF SHEAR WAVE VELOCITY PROFILES

Where measured shear wave velocity data are not available, shear wave velocity shall be estimated as a function of depth using correlations with suitable geotechnical parameters, including standard penetration test (SPT) blow counts, shear strength, overburden pressure, void ratio, or cone penetration test (CPT) tip resistance, measured at the site.

Site class based on estimated values of $\bar{v}_s$ shall be derived using $\bar{v}_s$, $\bar{v}_s/1.3$, and $1.3\bar{v}_s$ when correlation models are used to derive shear wave velocities. Where correlations derived for specific local regions can be demonstrated to have greater accuracy, factors less than 1.3 can be used if approved by the Authority Having Jurisdiction. If the different average velocities result in different site classes per Table 20.2-1, the most critical of the site classes for ground motion analysis at each period shall be determined by a geotechnical engineer, as described in Section 11.4.2.

Where the available data used to establish the shear wave velocity profile extends to depths less than 100 ft (30 m) but more than 50 ft (15 m), and the site geology is such that soft layers are unlikely to be encountered between 50 and 100 ft, the shear wave velocity of the last layer in the profile shall be extended to 100 ft for the calculation of $\bar{v}_s$ in Equation (20.4-1). Where the data does not extend to depths of 50 ft (15 m), default site classes, as described in Section 20.1, shall be used unless another site class can be justified on the basis of the site geology.

20.4 DEFINITIONS OF SITE CLASS PARAMETERS

The definitions presented in this section shall apply to the upper 100 ft (30 m) of the site profile. Profiles containing distinct soil and rock layers shall be subdivided into those layers designated by a number that ranges from 1 to n at the bottom, where there is a total of n distinct layers in the upper 100 ft (30 m). The symbol i refers to any one of the layers between 1 and n.

20.4.1 $\bar{v}_s$, Average Shear Wave Velocity The average shear wave velocity, $\bar{v}_s$, shall be determined in accordance with the following formula:

$$\bar{v}_s = \frac{\sum_{i=1}^{n} d_i}{\sum_{i=1}^{n} \frac{d_i}{v_{si}}} \tag{20.4-1}$$

where

d_i = Thickness of any layer between 0 and 100 ft (30 m),
v_{si} = Shear wave velocity in ft/s (m/s), and
$\sum_{n}^{i=1} d_i$ = 100 ft (30 m).

20.5 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

See Chapter 23 for the list of consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

@seismicisolation
@seismicisolation

CHAPTER 21
SITE-SPECIFIC GROUND MOTION PROCEDURES FOR SEISMIC DESIGN

21.1 SITE RESPONSE ANALYSIS

The requirements of Section 21.1 shall be satisfied where site response analysis is performed or required by Section 11.4.7. The analysis shall be documented in a report.

21.1.1 Base Ground Motions An MCE_R response spectrum shall be developed for a base condition consisting of bedrock, or when bedrock is very deep, firm soil conditions below softer surficial layers, using the procedure of Sections 11.4.6 or 21.2. Unless a site-specific ground motion hazard analysis described in Section 21.2 is carried out, the MCE_R base response spectrum shall be developed using the procedure of Section 11.4.6, assuming a site condition representative of the geological conditions at the base (represented by a base-condition average shear wave velocity, $\bar{v}_s$). At least five recorded or simulated horizontal ground motion acceleration time histories shall be selected from events that have magnitudes and fault distances that are consistent with those that control the MCE_R ground motion. Each selected time history shall be modified so that its response spectrum is, on average, approximately at the level of the MCE_R rock response spectrum over the period range of significance to structural response.

21.1.2 Site Condition Modeling A site response model based on low strain shear wave velocities, nonlinear or equivalent linear shear stress–strain relationships, and unit weights shall be developed. Low strain shear wave velocities shall be determined from field measurements at the site or from measurements from similar soils in the site vicinity. Nonlinear or equivalent linear shear stress–strain relationships and unit weights shall be selected on the basis of laboratory tests or published relationships for similar soils. The uncertainties in soil properties shall be estimated. Where very deep soil profiles make the development of a soil model to bedrock impractical, the model is permitted to be terminated where the soil stiffness is at least as great as the values used to define Site Class C in Chapter 20.

21.1.3 Site Response Analysis and Computed Results Base ground motion time histories shall be input to the soil profile as outcropping motions. Using appropriate computational techniques that treat nonlinear soil properties in a nonlinear or equivalent-linear manner, the response of the soil profile shall be determined and surface ground motion time histories shall be calculated. Ratios of 5% damped response spectra of surface ground motions to input base ground motions shall be calculated. The recommended surface MCE_R ground motion response spectrum shall not be lower than the MCE_R response spectrum of the base motion multiplied by the average surface-to-base response spectral ratios (calculated period by period) obtained from the site response analyses. The recommended surface ground motions that result from the analysis shall reflect consideration of sensitivity of response to uncertainty in soil properties, depth of soil model, and input motions.

21.2 RISK-TARGETED MAXIMUM CONSIDERED EARTHQUAKE (MCE_R) GROUND MOTION HAZARD ANALYSIS

The requirements of Section 21.2 shall be satisfied where a ground motion hazard analysis is performed or required by Section 11.4.7. The ground motion hazard analysis shall account for the regional tectonic setting, geology, and seismicity; the expected recurrence rates and maximum magnitudes of earthquakes on known faults and source zones; the characteristics of ground motion near source effects, if any, on ground motions; and the effects of subsurface site conditions on ground motions. The characteristics of subsurface site conditions shall be considered either using ground motion models that represent regional and local geology or in accordance with Section 21.1. The analysis shall incorporate current seismic interpretations, including uncertainties for models and parameter values for seismic sources and ground motions. If the spectral response accelerations predicted by the ground motion models do not represent the maximum response in the horizontal plane, then the response spectral accelerations computed from the hazard analysis shall be scaled by factors to increase the motions to the maximum response. If the ground motion models predict the geometric mean or similar metric of the two horizontal components, then the scale factors shall be 1.2 for periods less than, or equal to, 0.2 s, 1.25 for a period of 1.0 s, and 1.3 for periods greater than or equal to 10 s, unless it can be shown that other scale factors more closely represent the maximum response, in the horizontal plane, to the geometric mean of the horizontal components. Scale factors between these periods shall be obtained by linear interpolation. The analysis shall be documented in a report.

21.2.1 Probabilistic (MCE_R) Ground Motions The probabilistic spectral response accelerations shall be taken as the spectral response accelerations in the direction of maximum horizontal response represented by a 5% damped acceleration response spectrum that is expected to achieve a 1% probability of collapse within a 50-year period.

At each spectral response period for which the acceleration is computed, ordinates of the probabilistic ground motion response spectrum shall be determined from iterative integration of a site-specific hazard curve with a lognormal probability density function representing the collapse fragility (i.e., probability of collapse as a function of spectral response acceleration). The ordinate of the probabilistic ground motion response spectrum at each period shall achieve a 1% probability of collapse within a

@seismicisolation
@seismicisolation

50-year period for a collapse fragility that has (1) a 10% probability of collapse at said ordinate of the probabilistic ground motion response spectrum and (2) a logarithmic standard deviation value of 0.6.

21.2.2 Deterministic (MCE_R) Ground Motions The deterministic spectral response acceleration at each period shall be calculated as an 84th-percentile 5% damped spectral response acceleration in the direction of maximum horizontal response computed at that period. The largest such acceleration calculated for scenario earthquakes on all known faults within the region shall be used. The scenario earthquakes shall be determined from deaggregation for the probabilistic spectral response acceleration at each period. Scenario earthquakes contributing less than 10% of the largest contributor at each period shall be ignored.

For the purpose of this standard, the deterministic response spectral acceleration at each period shall be taken as not less than the deterministic lower limit response spectrum, of Table 21.2-1 of the site class, determined in accordance with the site class requirements of Section 11.4.2.

EXCEPTION: The deterministic ground motion response spectrum need not be calculated where the probabilistic ground motion response spectrum of 21.2.1 is, at all response periods, less than the deterministic lower limit response spectrum of Table 21.2-1 for the site class, determined in accordance with the site class requirements of Section 11.4.2.

21.2.3 Site-Specific MCE_R Response Spectrum The site-specific MCE_R spectral response acceleration at any period, S_{aM}, shall be taken as the lesser of the spectral response accelerations from the probabilistic ground motions of Section 21.2.1 and the deterministic ground motions of Section 21.2.2.

EXCEPTION: The site-specific MCE_R response spectrum may be taken as equal to the MCE_R response spectrum obtained from the USGS Seismic Design Geodatabase for the applicable site class.

The site-specific MCE_R spectral response acceleration at any period shall not be taken as less than 80% of the MCE_R response spectrum obtained from the USGS Seismic Design Geodatabase for the applicable site class.

21.2.3.1 Site Class F Sites For sites classified as Site Class F requiring site-specific analysis in accordance with Section 11.4.7, the site-specific MCE_R spectral response acceleration at any period shall not be less than 80% of the MCE_R response spectrum obtained from the USGS Seismic Design Geodatabase for Site Class E.

EXCEPTION: Where a different site class can be justified using the site-specific classification procedures of Section 20.3.3, a lower limit of 80% of S_{aM} for the justified site class shall be permitted to be used.

21.3 DESIGN RESPONSE SPECTRUM

The design spectral response acceleration at any period shall be determined from Equation (21.3-1):

$$S_a = \frac{2}{3} S_{aM} \tag{21.3-1}$$

where S_{aM} is the MCE_R spectral response acceleration obtained from Section 21.1 or 21.2.

@seismicisolation

21.4 DESIGN ACCELERATION PARAMETERS

Where the site-specific procedure is used to determine the design ground motion, in accordance with Section 21.3, the parameter S_{DS} shall be taken as 90% of the maximum spectral acceleration, S_a, obtained from the site-specific spectrum at any period within the range from 0.2 to 5 s, inclusive. The parameter S_{D1} shall be taken as 90% of the maximum value of the product, TS_a, for periods from 1 to 2 s for sites with $\bar{v}_s >$ 1,450 ft/s ($\bar{v}_s >$ 442 m/s) and for periods from 1 to 5 s for sites with $\bar{v}_s \leq$ 1,450 ft/s ($\bar{v}_s \leq$ 442 m/s), but not less than 100% of the value of S_a at 1 s. The parameters S_{MS} and S_{M1} shall be taken as 1.5 times S_{DS} and S_{D1}, respectively.

For use with the equivalent lateral force procedure, the site-specific spectral acceleration, S_a, at T shall be permitted to replace S_{D1}/T in Equation (12.8-3) and $S_{D1}/T_L/T^2$ in Equation (12.8-4). The parameter S_{DS} calculated per this section shall be permitted to be used in Equations (12.8-2), (12.8-5), (15.4-1), and (15.4-3). The mapped value of S_1 shall be used in Equations (12.8-6), (15.4-2), and (15.4-4).

21.5 MAXIMUM CONSIDERED EARTHQUAKE GEOMETRIC MEAN (MCE_G) PEAK GROUND ACCELERATION

21.5.1 Probabilistic MCE_G Peak Ground Acceleration The probabilistic geometric mean peak ground acceleration shall be taken as the geometric mean peak ground acceleration with a 2% probability of exceedance within a 50-year period.

21.5.2 Deterministic MCE_G Peak Ground Acceleration The deterministic geometric mean peak ground acceleration shall be calculated as the largest 84th-percentile geometric mean peak ground acceleration for scenario earthquakes on all known active faults within the site region. The scenario earthquakes shall be determined from deaggregation for the probabilistic geometric mean peak ground acceleration. Scenario earthquakes contributing less than 10% of the largest contributor shall be ignored. The deterministic geometric mean peak ground acceleration shall not be taken as lower than the value of PGA_G of Table 21.2-1 of the site class, determined in accordance with the site class requirements of Section 11.4.2.

21.5.3 Site-Specific MCE_G Peak Ground Acceleration PGA_M The site-specific MCE_G peak ground acceleration, PGA_M, shall be taken as the lesser of the probabilistic geometric mean peak ground acceleration of Section 21.5.1 and the deterministic geometric mean peak ground acceleration of Section 21.5.2. The site-specific MCE_G peak ground acceleration shall not be taken as less than 80% of the value of the MCE_G peak ground acceleration parameter PGA_M obtained from the USGS Seismic Design Geodatabase for the applicable site class.

21.6 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

CHAPTER 22
SEISMIC GROUND MOTION AND LONG-PERIOD TRANSITION MAPS

Contained in this chapter are Figures 22-1 through 22-8, which map the risk-targeted maximum considered earthquake (MCE_R) spectral response acceleration parameters, S_{MS} and S_{M1}, for default site conditions, based on the most critical spectral response acceleration of Site Classes C, CD, and D; Figures 22-9 through 22-13, which map the maximum considered earthquake geometric mean (MCE_G) peak ground acceleration parameter, PGA_M, for the default site conditions; and Figures 22-14 through 22-17, which map the long-period transition period parameter, T_L. In accordance with Section 11.4.3, S_{MS} and S_{M1} values for Site Classes A, B, BC, C, CD, D, DE, and E—as well as values of the MCE_R spectral response acceleration parameters, S_S and S_1, (for Site Class BC)—are contained in the USGS Seismic Design Geodatabase defined in Section 11.2; values of PGA_M for all the site classes are also contained in this geodatabase, in accordance with Section 11.8.3. For the definitions of these ground motion parameters, see Section 11.3.

These maps and the USGS Seismic Design Geodatabase were prepared by the US Geological Survey in collaboration with the Building Seismic Safety Council (BSSC) Provisions Update Committee and the ASCE 7 Seismic Subcommittee and have been updated for this standard.

Maps of T_L for Guam and the Northern Mariana Islands and for American Samoa are not provided because this parameter has not been developed for those islands via the same deaggregation computations done for the other US regions. Therefore, as in previous editions of this standard, the value of T_L shall be 12 s for those islands.

The following is a list of the maps contained in this chapter:

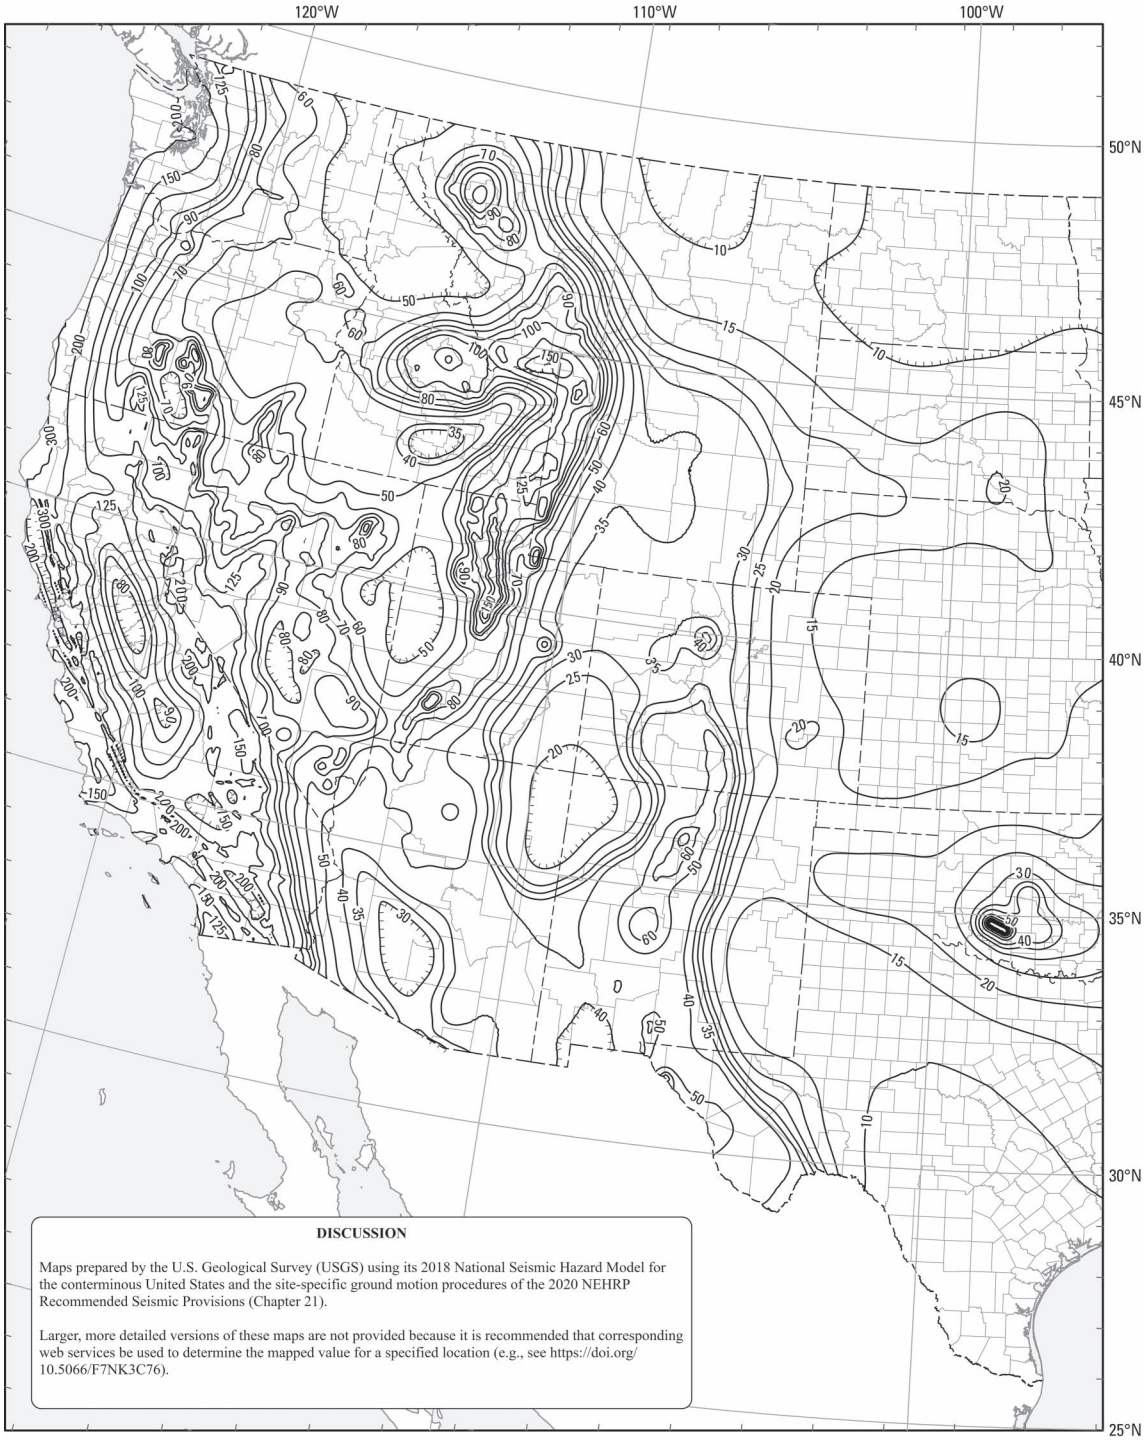

Figure 22-1 S_{MS} for the Default Site Conditions for the Conterminous United States

22.1 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

See Chapter 23 for the list of consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

@seismicisolation
@seismicisolation

Notes:

Maps prepared by USGS in collaboration with the FEMA-funded Building Seismic Safety Council (BSSC) and ASCE. The basis is explained in commentaries prepared by BSSC and ASCE and in the references.

Ground motion values contoured on these maps incorporate

- A target risk of structural collapse equal to 1% in 50 years based upon a generic structural fragility,
- A factor of 1.1 to adjust from a geometric mean to the maximum response regardless of direction, and
- Deterministic upper limits imposed near large, active faults, which are taken as 1.8 times the estimated median response to the characteristic earthquake for the governing fault (1.8 is used to represent the 84th percentile response), but not less than 150% g.

As such, the values are different from those on the uniform-hazard 2014 USGS National Seismic Hazard Maps posted at https://doi.org/10.5066/F7HT2MHG.

Larger, more detailed versions of these maps are not provided because it is recommended that the corresponding USGS web tool (https://doi.org/10.5066/F7NK3C76) be used to determine the mapped value for a specified location.

User Note: The USGS Seismic Design Geodatabase is available at the ASCE 7 Hazard Tool https://asce7hazardtool.online/ or an approved equivalent.

@seismicisolation

Notes:

Maps prepared by USGS in collaboration with the FEMA-funded BSSC and ASCE. The basis is explained in commentaries prepared by BSSC and ASCE and in the references.

Ground motion values contoured on these maps incorporate

- A target risk of structural collapse equal to 1% in 50 years based upon a generic structural fragility,
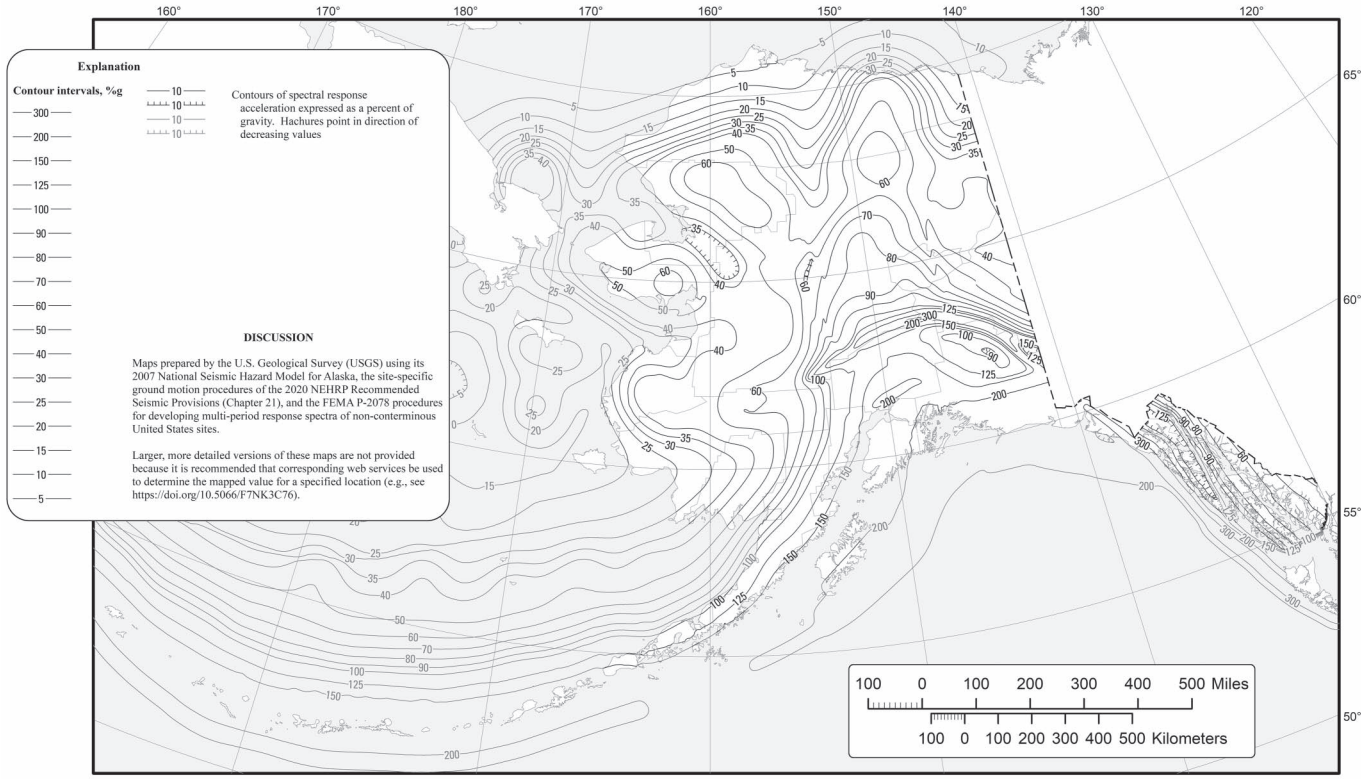
- A factor of 1.1 to adjust from a geometric mean to the maximum response regardless of direction, and
- Deterministic upper limits imposed near large, active faults, which are taken as 1.8 times the estimated median response to the characteristic earthquake for the fault (1.8 is used to represent the 84th percentile response), but not less than 150% g.



As such, the values are different from those on the uniform-hazard 2007 USGS National Seismic Hazard Maps for Alaska posted at https://doi.org/10.5066/F7HT2MHG.

Larger, more detailed versions of these maps are not provided because it is recommended that the corresponding USGS web tool (https://doi.org/10.5066/F7NK3C76) be used to determine the mapped value for a specified location.

User Note: The USGS Seismic Design Geodatabase is available at the ASCE 7 Hazard Tool https://asce7hazardtool.online/ or an approved equivalent.

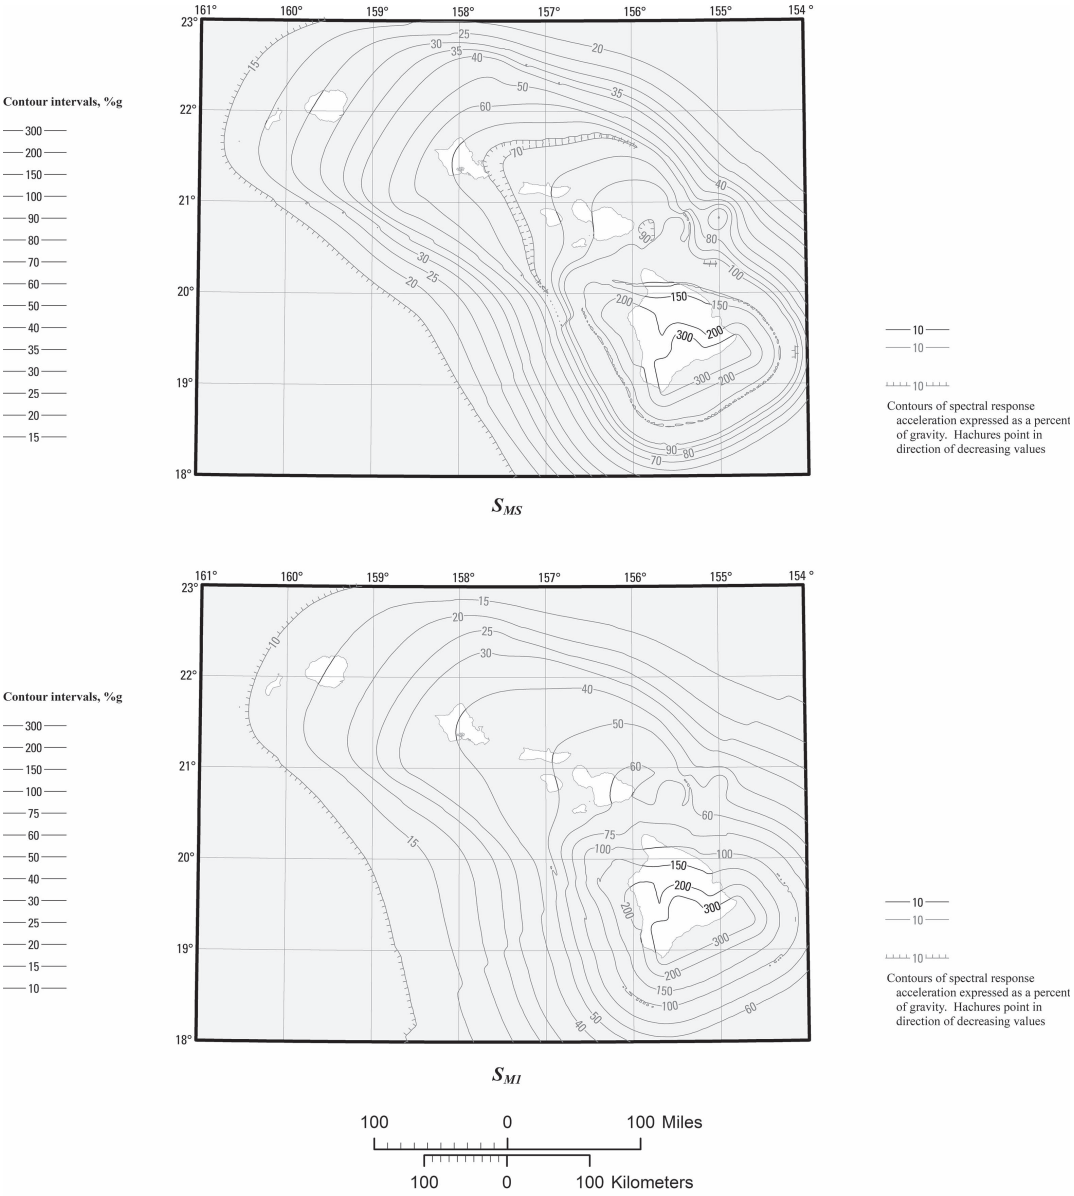
Notes:

Maps prepared by USGS in collaboration with the FEMA-funded BSSC and ASCE. The basis is explained in commentaries prepared by BSSC and ASCE and in the references.

Ground motion values contoured on these maps incorporate

- A target risk of structural collapse equal to 1% in 50 years based upon a generic structural fragility,
- A factor of 1.3 to adjust from a geometric mean to the maximum response regardless of direction, and
- Deterministic upper limits imposed near large, active faults, which are taken as 1.8 times the estimated median response to the characteristic earthquake for the fault (1.8 is used to represent the 84th percentile response), but not less than 60% g.



As such, the values are different from those on the uniform-hazard 2007 USGS National Seismic Hazard Maps for Alaska posted at https://doi.org/10.5066/F7HT2MHG.

Larger, more detailed versions of these maps are not provided because it is recommended that the corresponding USGS web tool (https://doi.org/10.5066/F7NK3C76) be used to determine the mapped value for a specified location.

CHAPTER 23
SEISMIC DESIGN REFERENCE DOCUMENTS

23.1 CONSENSUS STANDARDS AND OTHER REFERENCE DOCUMENTS

This section lists the consensus standards and other documents that shall be considered part of this standard to the extent referenced in Chapters 11 through 22. Those referenced documents identified by an asterisk (*) are not consensus standards; rather, they are documents developed within the industry and represent acceptable procedures for design and construction to the extent referred to in the specified section.

***AAMA 501.6**, *Recommended Dynamic Test Method for Determining the Seismic Drift Causing Glass Fallout from Window Wall, Curtain, and Storefront Systems*, American Architectural Manufacturers Association, 2018.

Cited in: Section 13.5.9.2

ACI 307, *Code Requirements for Reinforced Concrete Chimneys and Commentary*, American Concrete Institute, 2008.

CHAPTER 26
WIND LOADS: GENERAL REQUIREMENTS

26.1 PROCEDURES

26.1.1 Scope Buildings and other structures, including the main wind force resisting system (MWFRS) and all components and cladding (C&C) thereof, shall be designed and constructed to resist the wind loads determined in accordance with Chapters 26 through 31.

Risk Category III and IV buildings and other structures, including the MWFRS and all C&C thereof, shall also be designed and constructed to resist tornado loads determined in accordance with Chapter 32, as applicable.

The provisions of this chapter define basic wind parameters for use with other provisions contained in this standard.

User Note: A building or other structure designed for wind loads determined exclusively in accordance with Chapter 26 cannot be designated as a storm shelter without meeting additional critical requirements provided in the applicable building code and ICC 500, the *ICC/NSSA Standard for the Design and Construction of Storm Shelters*. See Commentary Section C26.1.1 for an in-depth discussion on Storm Shelters.

26.1.2 Permitted Procedures The design wind loads for buildings and other structures, including the MWFRS and C&C elements thereof, shall be determined using one of the procedures as specified in this section. An outline of the overall process for the determination of the wind loads, including section references, is provided in Figure 26.1-1.

Additional outlines and User Notes are provided at the beginning of Chapters 27 through 31 for more detailed step-by-step procedures for determining the wind loads.

26.1.2.1 Main Wind Force Resisting System Wind loads for the MWFRS shall be determined using one of the following procedures:

1. Directional Procedure for buildings of all heights as specified in Chapter 27 for buildings meeting the requirements specified therein;
2. Envelope Procedure for low-rise buildings as specified in Chapter 28 for buildings meeting the requirements specified therein;
3. Directional Procedure for building appurtenances (rooftop structures and rooftop equipment) and other structures (such as solid freestanding walls and solid freestanding signs, chimneys, tanks, open signs, single-plane open frames, and trussed towers) as specified in Chapter 29; or
4. Wind Tunnel Procedure for all buildings and all other structures as specified in Chapter 31.

26.1.2.2 Components and Cladding Wind loads on C&C on all buildings and other structures shall be designed using one of the following procedures:

1. Analytical Procedures provided in Parts 1 through 5, as appropriate, of Chapter 30; or
2. Wind Tunnel Procedure as specified in Chapter 31.

26.1.3 Performance-Based Procedures Wind design of buildings and other structures using performance-based procedures shall be permitted subject to the approval of the Authority Having Jurisdiction. The performance-based wind design procedures used shall, at a minimum, conform to Section 1.3.1.3.

26.2 DEFINITIONS

The following definitions apply to the provisions of Chapters 26 through 31.

APPROVED: Acceptable to the Authority Having Jurisdiction.

ASCE WIND DESIGN GEODATABASE: The ASCE database (version 2022-1.0) of geocoded wind speed design data.

User Note: The ASCE Wind Design Geodatabase of geocoded wind speed design data is available at https://asce7hazardtool.online/.

ATTACHED CANOPY: A horizontal (maximum slope of 2%) patio cover attached to the building wall at any height; it is different from an overhang, which is an extension of the roof surface.

BASIC WIND SPEED, *V*: Three-second gust speed at 33 ft (10 m) above the ground in Exposure C (see Section 26.7.3) as determined in accordance with Section 26.5.1.

BUILDING, ELEVATED: A building supported on structural elements where wind can pass beneath the building.

BUILDING, ENCLOSED: A building that has the total area of openings in each wall that receives positive external pressure less than or equal to 4 ft^2 (0.37 m^2) or 1% of the area of that wall, whichever is smaller. This condition is expressed for each wall by the following equation:

$$A_o < 0.01A_g \text{ or } 4\text{ ft}^2\ (0.37\text{ m}^2), \text{ whichever is smaller,}$$

where A_o and A_g are as defined for Open Buildings.

BUILDING, LOW-RISE: An enclosed, partially enclosed, or partially open building that complies with the following conditions:

@seismicisolation

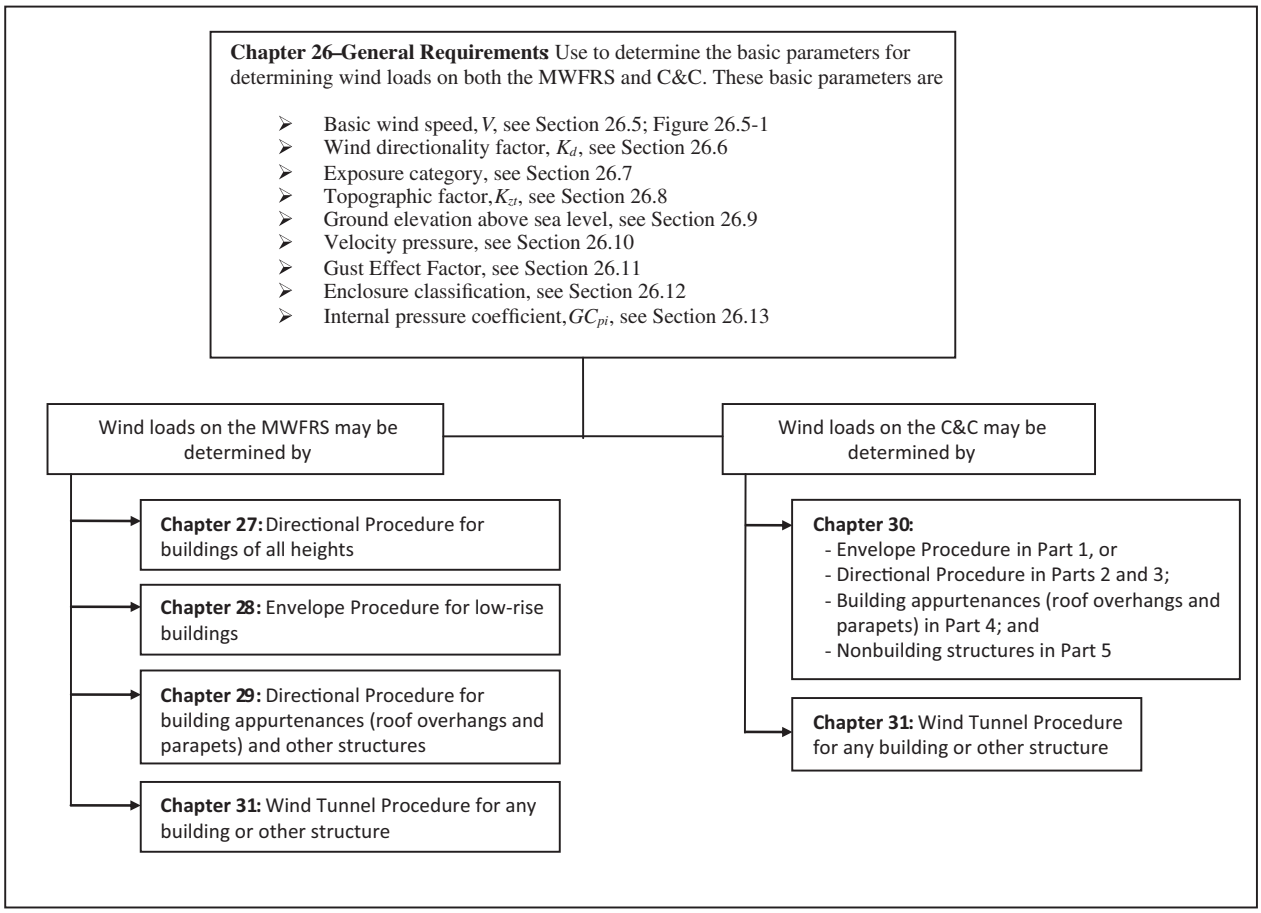

Figure 26.1-1. Outline of process for determining wind loads.

Note: Additional outlines and User Notes are provided at the beginning of each chapter for more detailed step-by-step procedures for determining the wind loads.

1. Mean roof height h less than or equal to 60 ft (18 m), and
2. Mean roof height h does not exceed the least horizontal dimension.

BUILDING, OPEN: A building that has each wall at least 80% open. This condition is expressed for each wall by the equation $A_o \geq 0.8A_g$

where A_o is the total area of openings in a wall that receives positive external pressure, ft^2 (m^2), and A_g is the gross area of that wall in which A_o is identified, ft^2 (m^2).

BUILDING, PARTIALLY ENCLOSED: A building that complies with both of the following conditions:

1. Total area of openings in a wall that receives positive external pressure exceeds the sum of the areas of openings in the balance of the building envelope (walls and roof) by more than 10%.
2. Total area of openings in a wall that receives positive external pressure exceeds 4 ft^2 (0.37 m^2) or 1% of the area of that wall, whichever is smaller, and the percentage of openings in the balance of the building envelope does not exceed 20%.

These conditions are expressed by the following equations:

$$A_o > 1.10A_{oi}$$

$$A_o > 4 \text{ ft}^2 (0.37 \text{ m}^2) \text{ or}$$

$$> 0.01A_g, \text{ whichever is smaller, and } A_{oi}/A_{gi} \leq 0.20$$

where A_o and A_g are as defined for open buildings; A_{oi} is the sum of the areas of openings in the building envelope (walls and roof), not including A_o, ft^2 (m^2); and A_{gi} is the sum of the gross surface areas of the building envelope (walls and roof), not including A_g, ft^2 (m^2).

BUILDING, PARTIALLY OPEN: A building that does not comply with the requirements for open, partially enclosed, or enclosed buildings.

BUILDING, TORSIONALLY REGULAR UNDER WIND LOAD: A building with the MWFRS about each principal axis proportioned so that the maximum displacement at each story under Case 2, the torsional wind load case, of Figure 27.3-8 does not exceed the maximum displacement at the same location under Case 1 of Figure 27.3-8, the basic wind load case.

BUILDING ENVELOPE: Cladding, roofing, exterior walls, glazing, door assemblies, window assemblies, skylight assemblies, and other components enclosing the building.

BUILDING OR OTHER STRUCTURE, FLEXIBLE: Slender buildings and other structures that have a fundamental natural frequency less than 1 Hz.

@seismicisolation

BUILDING OR OTHER STRUCTURE, REGULAR-SHAPED: A building or other structure that has no unusual geometrical irregularity in spatial form.

BUILDING OR OTHER STRUCTURE, RIGID: A building or other structure whose fundamental frequency is greater than or equal to 1 Hz.

COMPONENTS AND CLADDING (C&C): Elements of the building envelope or elements of building appurtenances and rooftop structures and equipment that do not qualify as part of the MWFRS.

DESIGN FORCE, *F*: Equivalent static force to be used in the determination of wind loads for other structures.

DESIGN PRESSURE, *p*: Equivalent static pressure to be used in the determination of wind loads for buildings.

DIAPHRAGM: Roof, floor, or other membrane or bracing system acting to transfer lateral forces to the vertical MWFRS. For analysis under wind loads, diaphragms constructed of untopped steel decks, concrete-filled steel decks, and concrete slabs, each having a span-to-depth ratio of 2 or less, shall be permitted to be idealized as *rigid*. Diaphragms constructed of wood structural panels are permitted to be idealized as *flexible*.

DIRECTIONAL PROCEDURE: A procedure for determining wind loads on buildings and other structures for specific wind directions, in which the external pressure coefficients used are based on past wind tunnel testing of prototypical building models for the corresponding direction of wind.

EAVE HEIGHT, h_e: The distance from the ground surface adjacent to the building to the roof eave line at a particular wall. If the height of the eave varies along the wall, the average height shall be used.

EFFECTIVE WIND AREA, *A*: The area used to determine the external pressure coefficient, (GC_p) and (GC_{rn}). For C&C elements, the effective wind area in Figures 30.3-1 through 30.3-7, 30.4-1, 30.5-1, and 30.7-1 through 30.7-3 is the span length multiplied by an effective width that need not be less than one-third the span length. For rooftop solar arrays, the effective wind area in Figure 29.4-7 is equal to the tributary area for the structural element being considered, except that the width of the effective wind area need not be less than one-third its length. For cladding fasteners, the effective wind area shall not be greater than the area that is tributary to an individual fastener.

ENVELOPE PROCEDURE: A procedure for determining wind load cases on buildings in which pseudoexternal pressure coefficients are derived from past wind tunnel testing of prototypical building models successively rotated through 360 degrees, such that the pseudopressure cases produce key structural actions (e.g., uplift, horizontal shear, and bending moments) that envelop their maximum values among all possible wind directions.

ESCARPMENT: With respect to topographic effects in Section 26.8, a cliff or steep slope generally separating two levels or gently sloping areas (see Figure 26.8-1). Also known as a scarp.

FREE ROOF: A roof with a configuration generally conforming to those shown in Figures 27.3-4 through 27.3-6 (monoslope, pitched, or troughed) in an open building with no enclosing walls underneath the roof surface.

GLAZING: Glass or transparent or translucent plastic sheet used in windows, doors, skylights, or curtain walls.

GLAZING, IMPACT-RESISTANT: Glazing that has been shown by testing to withstand the impact of test missiles. See Section 26.12.3.2.

HILL: With respect to topographic effects in Section 26.8, a land surface characterized by strong relief in any horizontal direction (see Figure 26.8-1).

HURRICANE-PRONE REGIONS: Areas vulnerable to hurricanes; in the United States and its territories, these are defined as

1. The US Atlantic Ocean and Gulf of Mexico coasts where the basic wind speed for Risk Category II buildings is greater than 115 mi/h (51.4 m/s); and
2. Hawaii, Puerto Rico, Guam, US Virgin Islands, Northern Mariana Islands, and American Samoa.

IMPACT-PROTECTIVE SYSTEM: Construction that has been shown by testing to withstand the impact of test missiles and that is applied, attached, or locked over exterior glazing. See Section 26.12.3.2.

MAIN WIND FORCE RESISTING SYSTEM (MWFRS): An assemblage of structural elements assigned to provide support and stability for the overall building or other structure. The system generally receives wind loading from more than one surface.

MEAN ROOF HEIGHT, *h*: The average of the roof eave height and the height to the highest point on the roof surface, except that, for roof angles less than or equal to 10 degrees, the mean roof height is permitted to be taken as the roof eave height.

OPENINGS: Holes that allow air to flow through the building envelope during a design wind event.

RECOGNIZED LITERATURE: Published research findings and technical papers that are approved.

RIDGE: With respect to topographic effects in Section 26.8, an elongated crest of a hill characterized by strong relief in two directions (see Figure 26.8-1).

ROOFTOP SOLAR PANEL: A device to receive solar radiation and convert it into electricity or heat energy. Typically, this is a photovoltaic module or solar thermal panel.

SOLAR ARRAY: Any number of rooftop solar panels grouped closely together.

WIND-BORNE DEBRIS REGIONS: Areas within hurricane-prone regions where impact protection is required for glazed openings. See Section 26.12.3.

WIND TUNNEL PROCEDURE: A procedure for determining wind loads on buildings and other structures in which pressures and/or forces and moments are determined for each wind direction considered, from a model of the building or other structure and its surroundings, in accordance with Chapter 31.

26.3 SYMBOLS

The following symbols apply only to the provisions of Chapters 26 through 31:

A = Effective wind area, ft^2 (m^2)
A_f = Area of open buildings and other structures either normal to the wind direction or projected on a plane normal to the wind direction, ft^2 (m^2)
A_g = Gross area of that wall in which A_o is identified, ft^2 (m^2)
A_{gi} = Sum of the gross surface areas of the building envelope (walls and roof) not including A_g, ft^2 (m^2)
A_n = Normalized wind area for rooftop solar panels in Figure 29.4-7, ft^2 (m^2)
A_o = Total area of openings in a wall that receives positive external pressure, ft^2 (m^2)

@seismicisolation

A_{og} = Total area of openings in the building envelope, ft^2 (m^2)

A_{oi} = Sum of the areas of openings in the building envelope (walls and roof) not including A_o, ft^2 (m^2)

A_s = Gross area of the solid freestanding wall or solid sign, ft^2 (m^2)

A_1, A_2 = Effective wind area for use with ground-mounted solar panels in Figure 29.4-11, ft^2 (m^2)

a = Width of pressure coefficient zone, ft (m)

a_B = Width of pressure coefficient zone for elevated buildings, ft (m)

B = Horizontal dimension of a building measured normal to wind direction, ft (m)

$\overline{b}$ = Mean hourly wind speed factor in Equation (26.11-16), from Table 26.11-1

$\hat{b}$ = Three-second gust speed factor from Table 26.11-1

C_f = Force coefficient to be used in determination of wind loads for other structures

C_N = Net pressure coefficient to be used in determination of wind loads for open buildings

C_p = External pressure coefficient to be used in determination of wind loads for buildings

c = Turbulence intensity factor in Equation (26.11-7), from Table 26.11-1

D = Diameter of a circular structure or member, ft (m)

D' = Depth of protruding elements such as ribs and spoilers, ft (m)

d_p = Horizontal distance of Zone 2 for ground-mounted solar panels in Figure 29.4.9, ft (m)

d_s = Horizontal offset for ground-mounted solar panels in Figure 29.4.9, ft (m)

d_1 = For rooftop solar arrays, horizontal distance orthogonal to the panel edge to an adjacent panel or the building edge, ignoring any rooftop equipment in Figure 29.4-7, ft (m)

d_2 = For rooftop solar arrays, horizontal distance from the edge of one panel to the nearest edge in the next row of panels in Figure 29.4-7, ft (m)

F = Design wind force for other structures, lb (N)

F_n = Normal force for ground-mounted solar panels in Figure 29.4-9, lb (N)

G = Gust-effect factor

G_f = Gust-effect factor for MWFRS of flexible buildings and other structures

$(GC_{gn_{\text{dynamic}}})$ = Dynamic net pressure coefficient for ground-mounted solar panels from Figure 29.4-11

$(GC_{gm_{\text{dynamic}}})$ = Dynamic moment coefficient for ground-mounted solar panels from Figure 29.4-11

$(GC_{gn_{\text{static}}})$ = Static net pressure coefficient for ground-mounted solar panels from Figure 29.4-10

$(GC_{gm_{\text{static}}})$ = Static moment coefficient for ground-mounted solar panels from Figure 29.4-10

(GC_p) = Product of external pressure coefficient and gust-effect factor to be used in determination of wind loads for buildings

(GC_{pf}) = Product of the equivalent external pressure coefficient and gust-effect factor to be used in determination of wind loads for MWFRS of low-rise buildings

(GC_{pi}) = Product of internal pressure coefficient and gust-effect factor to be used in determination of wind loads for buildings

(GC_{pn}) = Combined net pressure coefficient for a parapet

(GC_r) = Product of external pressure coefficient and gust-effect factor to be used in determination of wind loads for rooftop structures

(GC_{rn}) = Net pressure coefficient for rooftop solar panels in Equations (29.4-4) and (29.4-5)

$(GC_{rn})_{nom}$ = Nominal net pressure coefficient for rooftop solar panels determined from Figure 29.4-7

g_Q = Peak factor for background response in Equations (26.11-6) and (26.11-10)

g_R = Peak factor for resonant response in Equation (26.11-10)

g_v = Peak factor for wind response in Equations (26.11-6) and (26.11-10)

H = Height of hill, ridge, or escarpment in Figure 26.8-1, ft (m)

h = Mean roof height of a building or height of other structure, except that eave height shall be used for roof angle θ less than or equal to 10 degrees, in ft (m)

h_B = Height above grade of the bottom surface of the elevated building, ft (m)

h_c = Height of the solid cylinder, ft (m)

h_e = Roof eave height at a particular wall, or the average height if the eave varies along the wall

h_p = Height to top of parapet in Figures 27.5-2 and 30.6-1

h_{pt} = Mean parapet height above the adjacent roof surface for use with Equation (29.4-5), ft (m)

h_1 = Height of a solar panel above the roof at the lower edge of the panel, ft (m)

h_2 = Height of a solar panel above the roof at the upper edge of the panel, ft (m)

$I_{\bar{z}}$ = Intensity of turbulence from Equation (26.11-7)

K_1, K_2, K_3 = Multipliers in Figure 26.8-1 to obtain K_{zt}

K_d = Wind directionality factor from Section 26.6 and Table 26.6-1

K_e = Ground elevation factor

K_h = Velocity pressure exposure coefficient evaluated at height $z = h$

K_z = Velocity pressure exposure coefficient evaluated at height z

K_{zt} = Topographic factor as defined in Section 26.8

L = Horizontal dimension of a building measured parallel to the wind direction, ft (m)

L_b = Normalized building length, for use with Figure 29.4-7, ft (m)

L_c = Panel chord length for ground-mounted solar panels in Figure 29.4-9, ft (m)

L_h = Distance upwind of crest of hill, ridge, or escarpment in Figure 26.8-1 to where the difference in ground elevation is half the height of the hill, ridge, or escarpment, ft (m)

L_p = Panel chord length for use with rooftop solar panels in Figure 29.4-7, ft (m)

L_r = Horizontal dimension of return corner for a solid freestanding wall or solid sign from Figure 29.3-1, ft (m)

L_z = Integral length scale of turbulence, ft (m)

ℓ = Integral length scale factor from Table 26.11-1, ft (m)

M_c = Moment for ground-mounted solar panels in Figure 29.4.9, lb-ft (N-m)

N_1 = Reduced frequency from Equation (26.11-14)

@seismicisolation

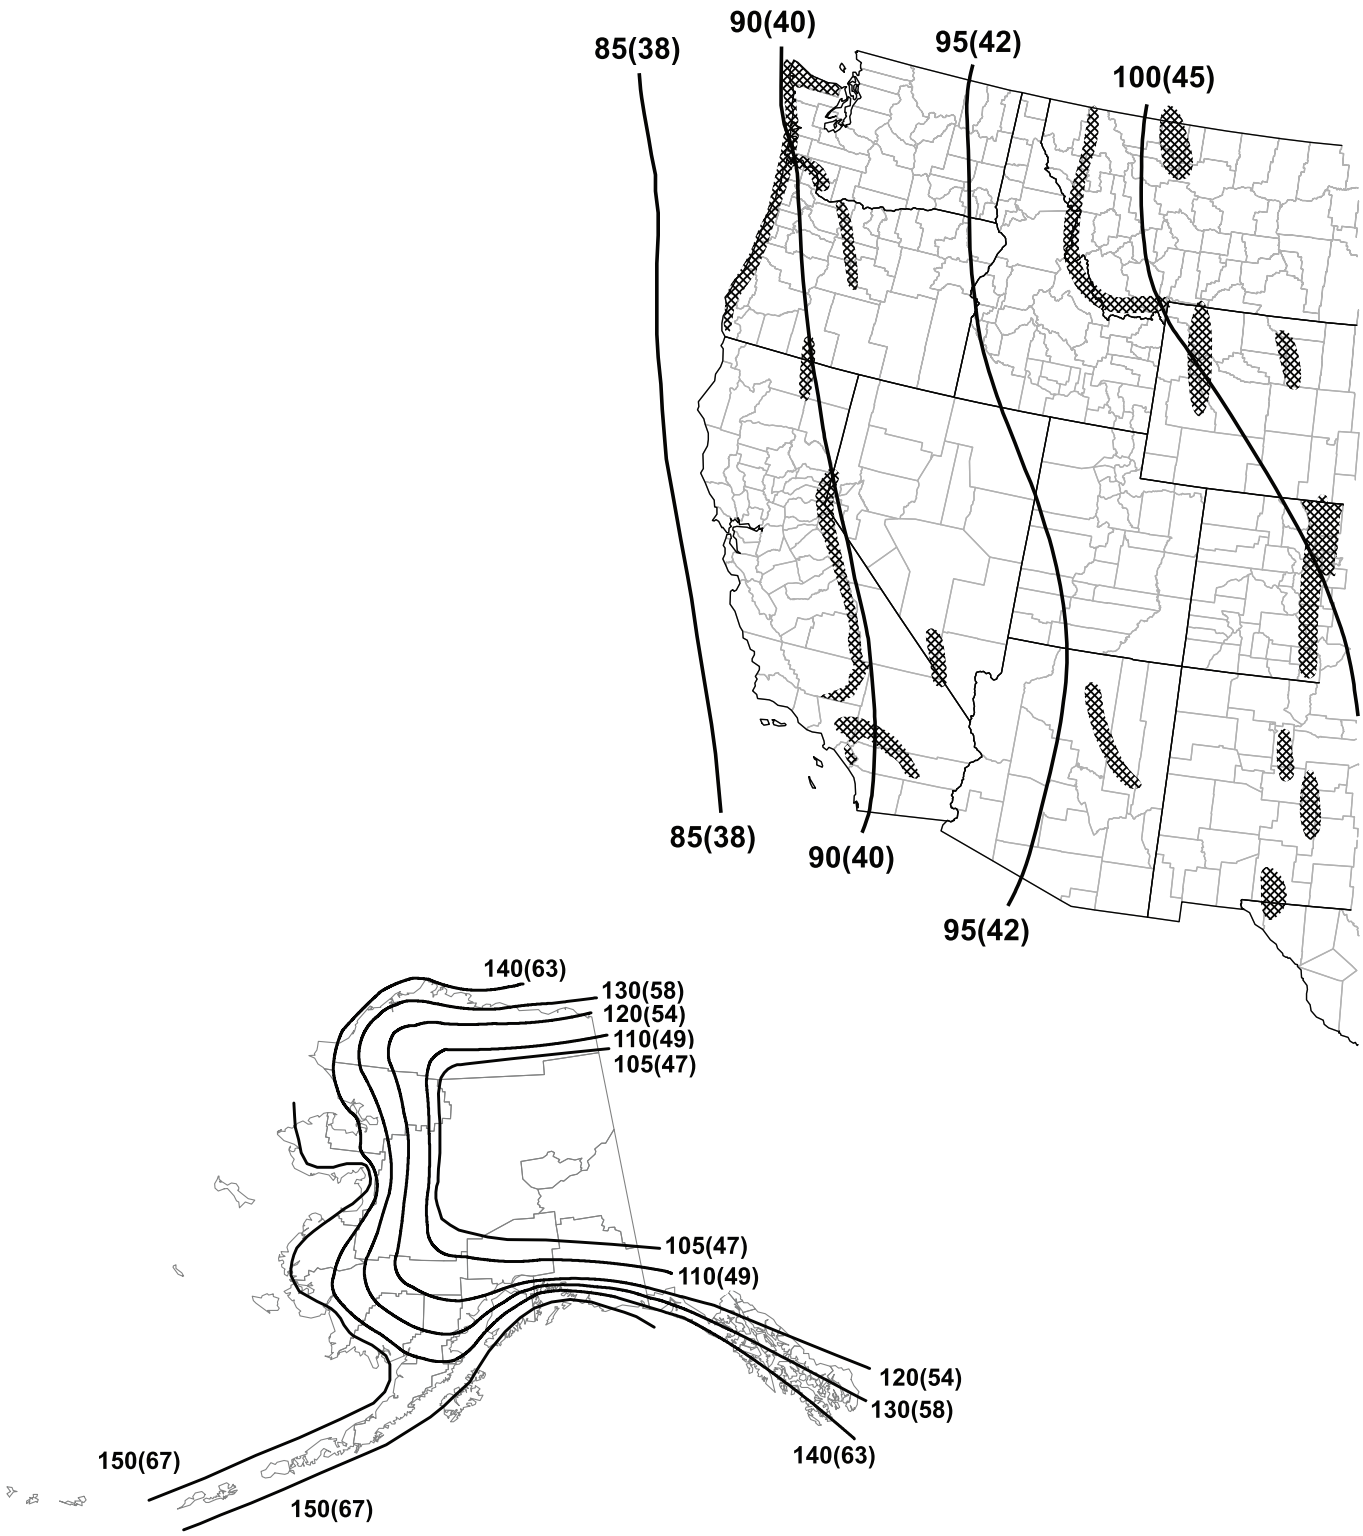
N_s = Reduced frequency for ground-mounted solar panels
n = Lowest natural frequency for ground-mounted solar panels, Hz
η_1 = Fundamental natural frequency, Hz
η_a = Approximate lower bound natural frequency from Section 26.11.2, Hz
p = Design pressure to be used in determination of wind loads for buildings, lb/ft^2 (N/m^2)
P_L = Wind pressure acting on leeward face in Figure 27.3-8, lb/ft^2 (N/m^2)
Q = Background response factor from Equation (26.11-8)
q = Velocity pressure, lb/ft^2 (N/m^2)
q_h = Velocity pressure evaluated at height $z = h$, lb/ft^2 (N/m^2)
q_i = Velocity pressure for internal pressure determination, lb/ft^2 (N/m^2)
q_p = Velocity pressure at top of parapet, lb/ft^2 (N/m^2)
q_z = Velocity pressure evaluated at height z above ground, lb/ft^2 (N/m^2)
R = Resonant response factor from Equation (26.11-12)
r = Rise-to-span ratio for arched roofs
R_B, R_h, R_L = Values from Equations (26.11-15a) and (26.11-15b)
R_i = Reduction factor from Equation (26.13-1)
R_n = Value from Equation (26.11-13)
S = Center-to-center row spacing for ground-mounted solar panels in Figure 29.4-9, ft (m)
S_L = Open distance in longitudinal direction for ground-mounted solar panels in Figure 29.4-9, ft (m)
S_T = Open distance in transverse direction for ground-mounted solar panels in Figure 29.4-9, ft (m)
s = Vertical dimension of the solid freestanding wall or solid sign from Figure 29.3-1, ft (m)
s_p = Gap between adjacent panels for ground-mounted solar panels in Figure 29.4-9, ft (m)
V = Basic wind speed obtained from Figures 26.5-1A through 26.5-1D, mi/h (m/s); the basic wind speed corresponds to a 3 s gust speed at 33 ft (10 m) above the ground in Exposure Category C
V_i = Unpartitioned internal volume, in ft^3 (m^3)
$\overline{V}_{\bar{z}}$ = Mean hourly wind speed at height $\bar{z}$, in ft/s (m/s)
W = Width of building in Figures 30.3-3, 30.3-5A, and 30.3-5B and width of span in Figures 30.3-4 and 30.3-6, ft (m)
W_g = Shortest row length for ground-mounted solar panels in Figure 29.4-9, ft (m)
W_L = Width of a building on its longest side in Figure 29.4-7, ft (m)
W_S = Width of a building on its shortest side in Figure 29.4-7, ft (m)
x = Distance upwind or downwind of crest in Figure 26.8-1, ft (m)
z = Height above ground level, ft (m)
$\overline{z}$ = Equivalent height of structure, ft (m)
z_e = Ground elevation above sea level, ft (m)
z_g = Nominal height of the atmospheric boundary layer used in this standard (values appear in Table 26.11-1)
$z_{\min}$ = Exposure constant from Table 26.11-1
α = 3-s gust-speed power law exponent from Table 26.11-1
$\hat{\alpha}$ = Reciprocal of α from Table 26.11-1
$\overline{\alpha}$ = Mean hourly wind-speed power law exponent in Equation (26.11-16) from Table 26.11-1
β = Damping ratio, percent critical for buildings or other structures
γ_c = Panel chord factor for use with rooftop solar panels in Equation (29.4-5)
γ_E = Array edge factor for use with rooftop solar panels in Figure 29.4-7 and Equations (29.4-4) and (29.4-5)
γ_p = Parapet height factor for use with rooftop solar panels in Equation (29.4-5)
ε = Ratio of solid area to gross area for solid freestanding wall, solid sign, open sign, face of a trussed tower, or lattice structure
$\overline{\varepsilon}$ = Integral length scale power law exponent in Equation (26.11-9) from Table 26.11-1
η = Value used in Equations (26.11-15a) and (26.11-15b); see Section 26.11.4
θ = Angle of plane of roof from horizontal, degrees
ν = Height-to-width ratio for solid sign
ω = Angle that the solar panel makes with the roof surface in Figure 29.4-7, or that a ground-mounted solar panel makes with the ground in Figure 29.4-9, degrees

26.4 GENERAL

26.4.1 Sign Convention Positive pressure acts toward the surface, and negative pressure acts away from the surface.

26.4.2 Critical Load Condition Values of external and internal pressures shall be combined algebraically to determine the most critical load.

26.4.3 Wind Pressures Acting on Opposite Faces of Each Building Surface In the calculation of design wind loads for the MWFRS and for C&C for buildings, the algebraic sum of the pressures acting on opposite faces of each building surface shall be taken into account.



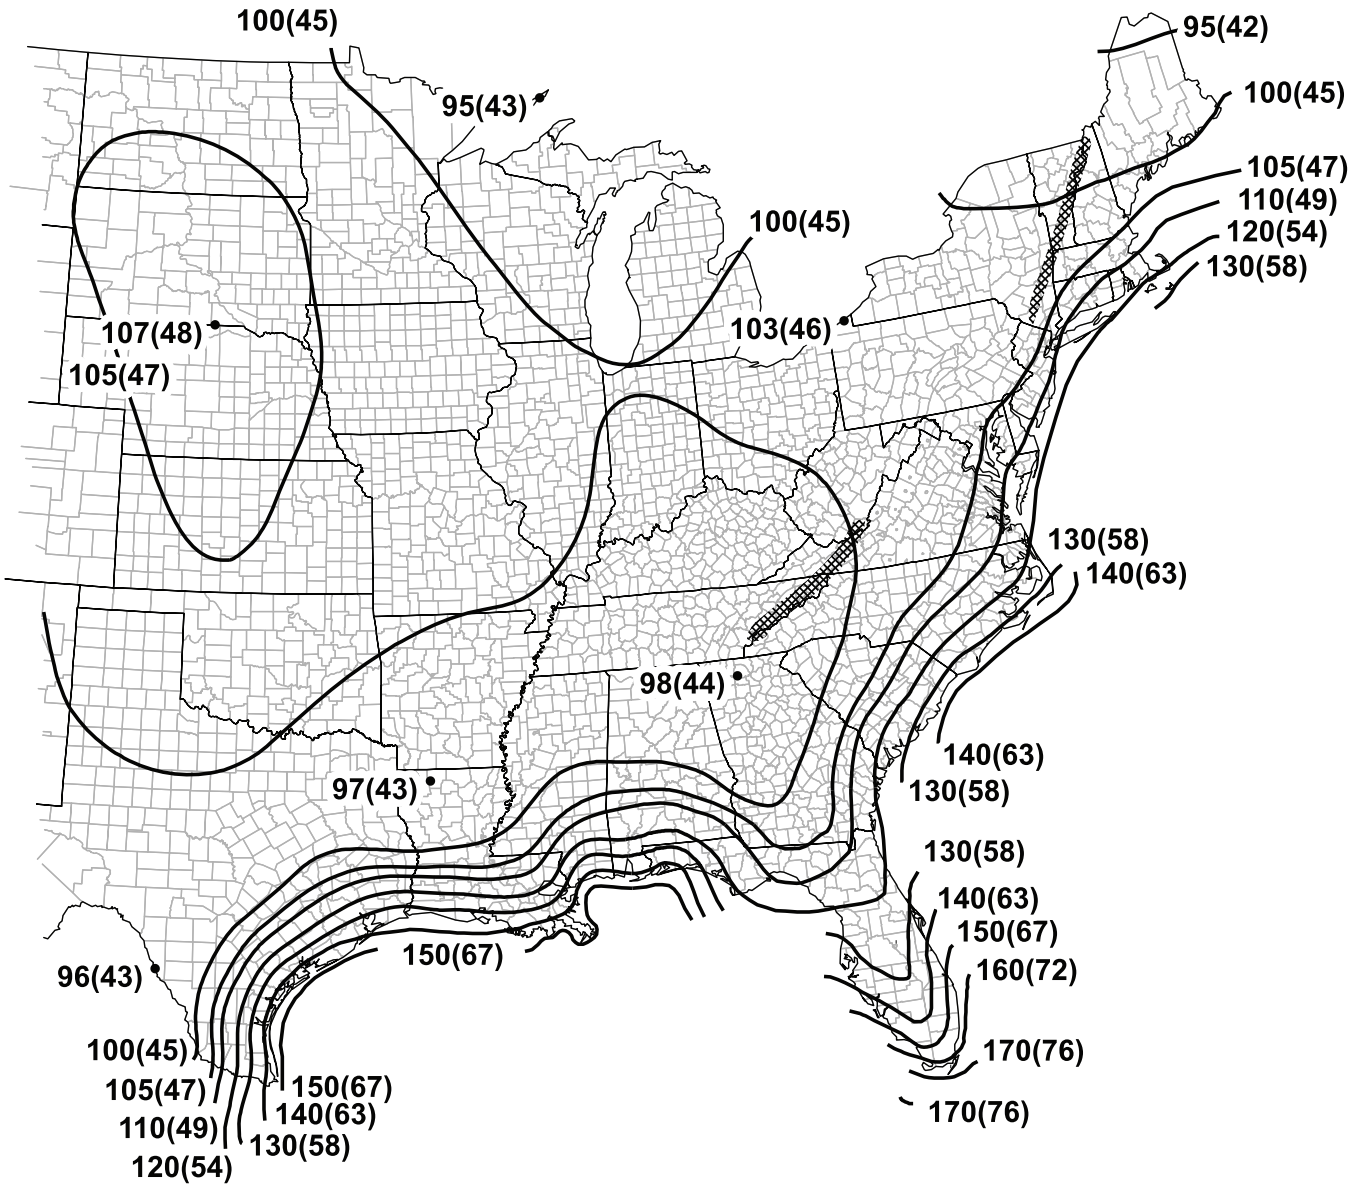
26.5 WIND HAZARD MAP

26.5.1 Basic Wind Speed The basic wind speed, V, used in the determination of design wind loads on buildings and other structures shall be determined from Figure 26.5-1 as follows, except as provided in Sections 26.5.2 and 26.5.3:

For Risk Category I buildings and structures, use Figure 26.5-1A.
For Risk Category II buildings and structures, use Figure 26.5-1B.
For Risk Category III buildings and structures, use Figure 26.5-1C.
For Risk Category IV buildings and structures, use Figure 26.5-1D.

Alternatively, it shall be permitted to use the basic wind speeds from the ASCE Wind Design Geodatabase for the contiguous United States, Alaska, and selected special wind regions.

@seismicisolation

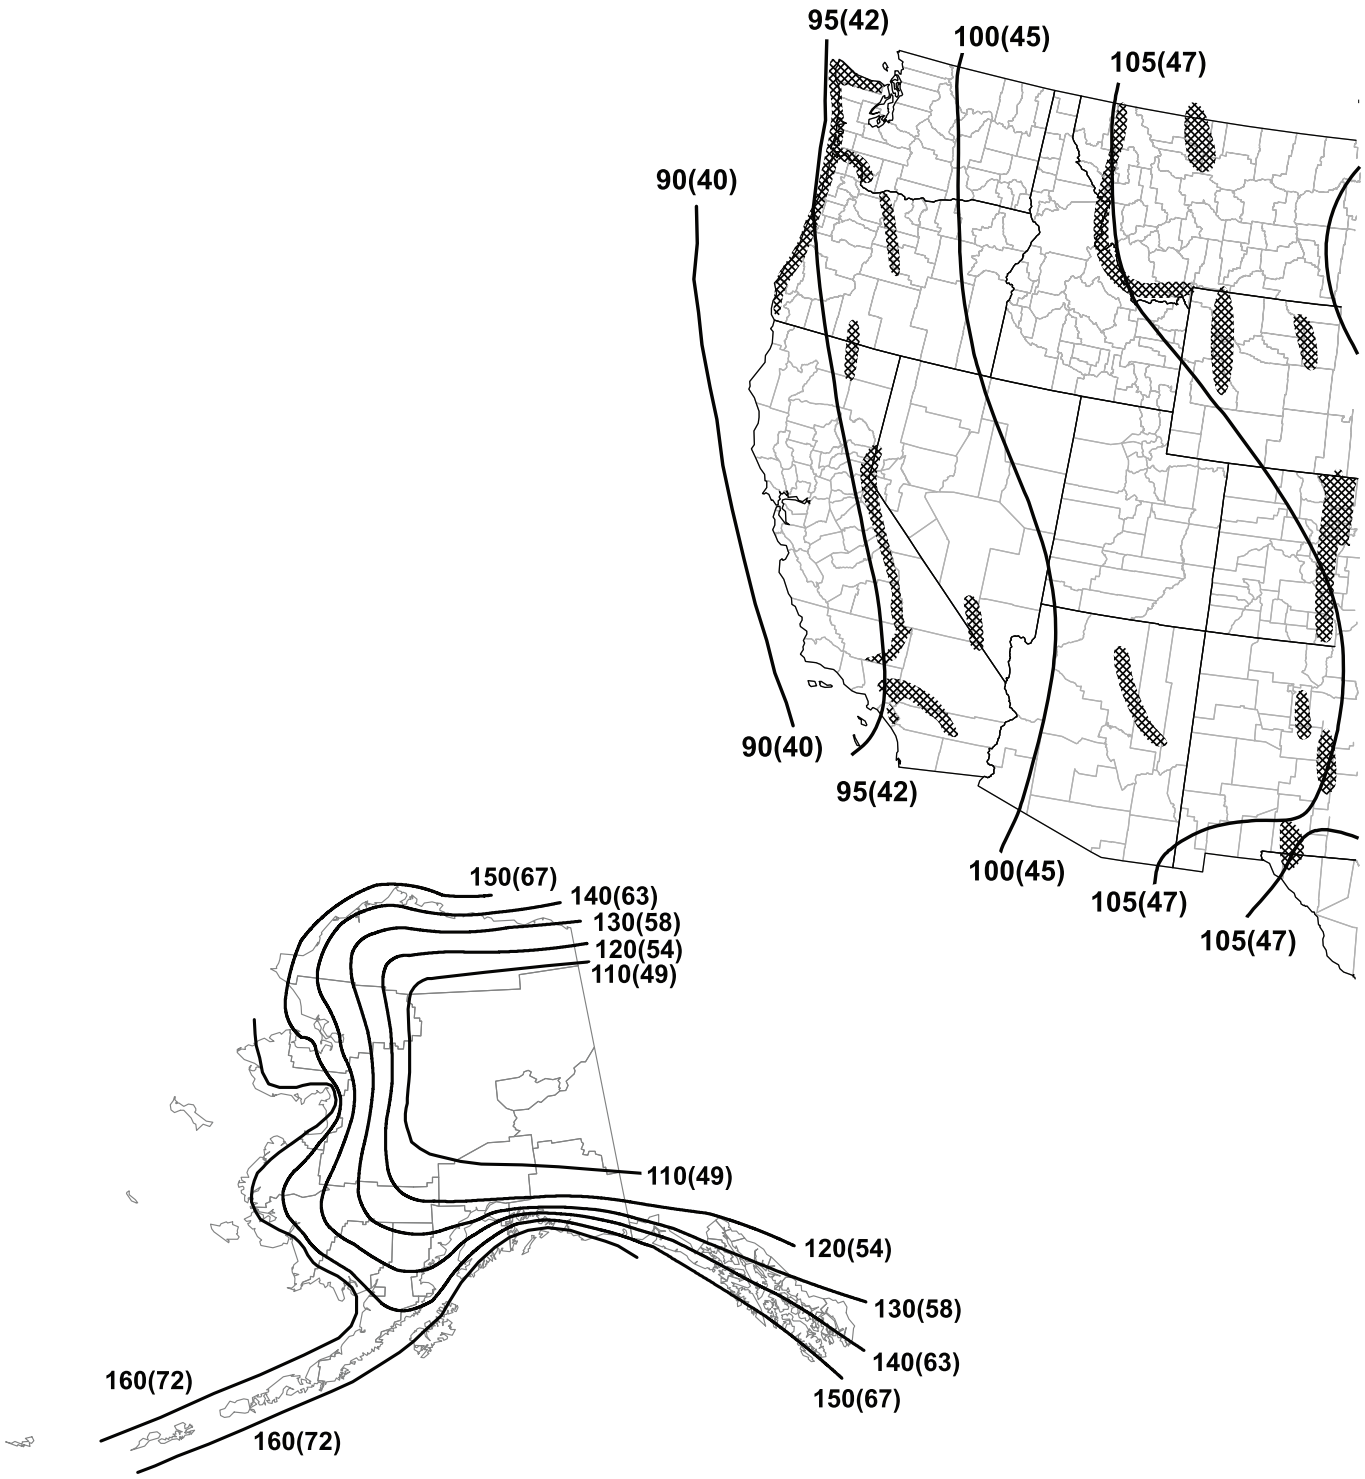


Notes:

1. Values are 3 s gust wind speeds in mi/h (m/s) at 33 ft (10 m) above ground for Exposure Category C.
2. Linear interpolation is permitted between contours. Point values are provided to aid with interpolation.
3. Islands, coastal areas, and land boundaries outside the last contour shall use the last wind speed contour.
4. Location-specific basic wind speeds shall be permitted to be determined using the ASCE Wind Design Geodatabase.

Figure 26.5-1A. Basic wind speeds for Risk Category I buildings and other structures.

@seismicisolation

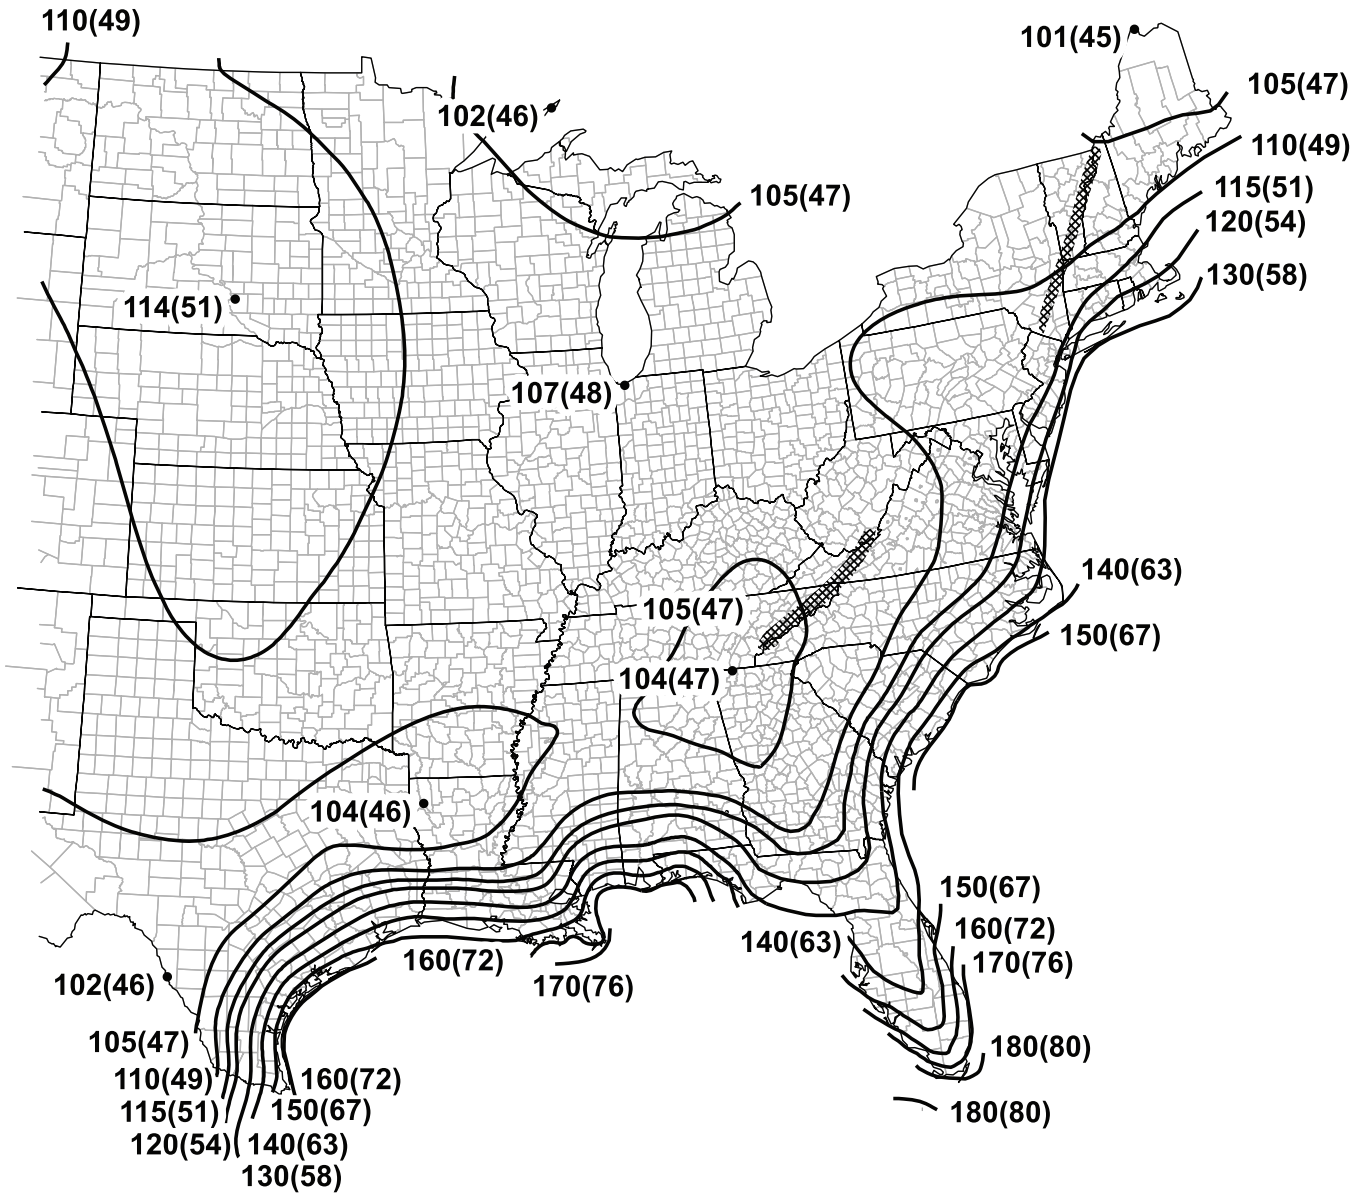


Location	V (mi/h)	V (m/s)
American Samoa	150	(67)
Guam & Northern Mariana Islands	180	(80)
Hawaii	ASCE Wind Design Geodatabase	
Puerto Rico	ASCE Wind Design Geodatabase	
U.S. Virgin Islands	ASCE Wind Design Geodatabase	

5. Wind speeds for Hawaii, US Virgin Islands, and Puerto Rico shall be determined from the ASCE Wind Design Geodatabase.
6. Mountainous terrain, gorges, ocean promontories, and special wind regions shall be examined for unusual wind conditions. Site-specific values for selected special wind regions shall be permitted to be determined using the ASCE Wind Design Geodatabase.
7. Wind speeds correspond to approximately a 15% probability of exceedance in 50 years (Annual Exceedance Probability = 0.00333, MRI = 300 years).
8. The ASCE Wind Design Geodatabase can be accessed at the ASCE 7 Hazard Tool (https://asce7hazardtool.online) or approved equivalent.

Figure 26.5-1A (*Continued*). Basic wind speeds for Risk Category I buildings and other structures.

@seismicisolation



Notes:

1. Values are 3 s gust wind speeds in mi/h (m/s) at 33 ft (10 m) above ground for Exposure Category C.
2. Linear interpolation is permitted between contours. Point values are provided to aid with interpolation.
3. Islands, coastal areas, and land boundaries outside the last contour shall use the last wind speed contour.
4. Location-specific basic wind speeds shall be permitted to be determined using the ASCE Wind Design Geodatabase.

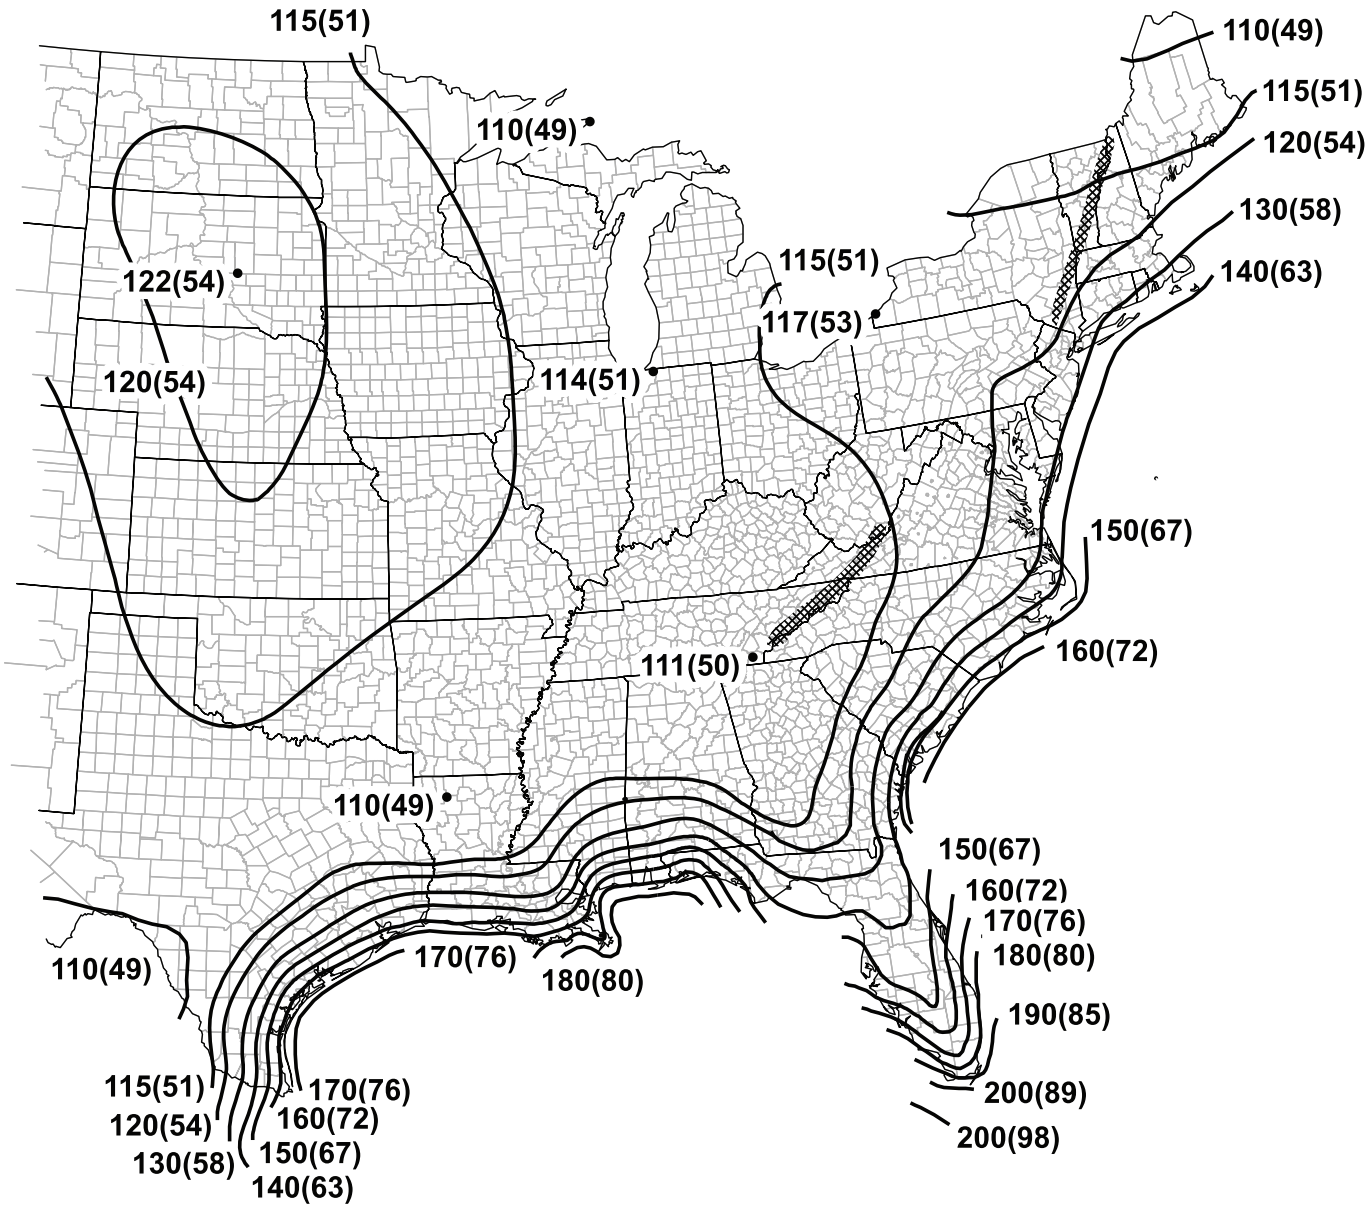
5. Wind speeds for Hawaii, US Virgin Islands, and Puerto Rico shall be determined from the ASCE Wind Design Geodatabase.
6. Mountainous terrain, gorges, ocean promontories, and special wind regions shall be examined for unusual wind conditions. Site-specific values for selected special wind regions shall be permitted to be determined using the ASCE Wind Design Geodatabase.
7. Wind speeds correspond to approximately a 15% probability of exceedance in 50 years (Annual Exceedance Probability = 0.00143, MRI = 700 years).
8. The ASCE Wind Design Geodatabase can be accessed at the ASCE 7 Hazard Tool (https://asce7hazardtool.online) or approved equivalent.

Figure 26.5-1B (*Continued*). Basic wind speeds for Risk Category II buildings and other structures.

@seismicisolation



Notes:

1. Values are 3 s gust wind speeds in mi/h (m/s) at 33 ft (10 m) above ground for Exposure Category C.
2. Linear interpolation is permitted between contours. Point values are provided to aid with interpolation.
3. Islands, coastal areas, and land boundaries outside the last contour shall use the last wind speed contour.
4. Location-specific basic wind speeds shall be permitted to be determined using the ASCE Wind Design Geodatabase.

7. Wind speeds correspond to approximately a 15% probability of exceedance in 50 years (Annual Exceedance Probability = 0.00033, MRI = 3,000 years).
8. The ASCE Wind Design Geodatabase can be accessed at the ASCE 7 Hazard Tool (https://asce7hazardtool.online) or approved equivalent.

Figure 26.5-1D (*Continued*). Basic wind speeds for Risk Category IV buildings and other structures.

@seismicisolation

Basic wind speeds for Hawaii, US Virgin Islands, and Puerto Rico shall be determined by using the ASCE Wind Design Geodatabase.

The ASCE Wind Design Geodatabase is available at the ASCE 7 Hazard Tool (https://asce7hazardtool.online), or approved equivalent.

The wind shall be assumed to come from any horizontal direction. The basic wind speed shall be increased where records or experience indicate that the wind speeds are higher than those reflected in Figure 26.5-1.

26.5.2 Special Wind Regions Mountainous terrain, gorges, and special wind regions shown in Figure 26.5-1 shall be examined for unusual wind conditions. The Authority Having Jurisdiction shall, if necessary, adjust the values given in Figure 26.5-1 to account for higher local wind speeds. Such adjustment shall be based on meteorological information and an estimate of the basic wind speed obtained in accordance with the provisions of Section 26.5.3.

Site-specific values for select special wind regions in the contiguous United States have been included in the ASCE 7 Wind Design Geodatabase. It shall be permitted to use the wind speed values for Special Wind Regions from the ASCE 7 Wind Design Geodatabase (https://asce7hazardtool.online/).

26.5.3 Estimation of Basic Wind Speeds from Regional Climatic Data In areas outside hurricane-prone regions, regional climatic data shall only be used in lieu of the basic wind speeds given in Figure 26.5-1 when (1) approved extreme-value statistical analysis procedures have been used in reducing the data, and (2) the length of record, sampling error, averaging time, anemometer height, data quality, and terrain exposure of the anemometer have been taken into account. Reduction in basic wind speed below that of Figure 26.5-1 shall be permitted.

In hurricane-prone regions, wind speeds derived from simulation techniques shall only be used in lieu of the basic wind speeds given in Figure 26.5-1 when approved simulation and extreme-value statistical analysis procedures are used. The use of regional wind-speed data obtained from anemometers is not permitted to define the hurricane wind-speed risk along the Gulf and Atlantic coasts, the Caribbean, or Hawaii.

When the basic wind speed is estimated from regional climatic data or simulation, the estimate shall correspond to the applicable mean recurrence interval, and the estimate shall be adjusted for equivalence to a 3 s gust wind speed at 33 ft (10 m) above ground in Exposure C.

26.6 WIND DIRECTIONALITY FACTOR

The wind directionality factor, K_d, shall be determined from Table 26.6-1 and shall be included in the wind loads calculated in Chapters 27 through 30. The effect of wind directionality in determining wind loads in accordance with Chapter 31 shall be based on a rational analysis of the wind speeds conforming to the requirements of Section 26.5.3 and of Section 31.4.3.

Table 26.6-1. Wind Directionality Factor, K_d.

Structure Type	Directionality Factor K_d
Buildings	
Main wind force resisting system	0.85
Components and cladding	0.85
Arched roofs	0.85
Circular domes	1.0*
Chimneys, tanks, and similar structures	
Square	0.90
Hexagonal	0.95
Octagonal	1.0*
Round	1.0*
Solid freestanding walls, roof top equipment, and solid freestanding and attached signs	0.85
Open signs and single-plane open frames	0.85
Trussed towers	
Triangular, square, or rectangular	0.85
All other cross sections	0.95

*Directionality factor $K_d = 0.95$ shall be permitted for round or octagonal structures with nonaxisymmetric structural systems.

26.7 EXPOSURE

For each wind direction considered, the upwind exposure shall be based on ground surface roughness that is determined from natural topography, vegetation, and constructed facilities.

26.7.1 Wind Directions and Sectors For each selected wind direction at which the wind loads are to be determined, the exposure of the building or structure shall be determined for the two upwind sectors extending 45 degrees on either side of the selected wind direction. The exposure in these two sectors shall be determined in accordance with Sections 26.7.2 and 26.7.3, and the exposure the use of which would result in the highest wind loads shall be used to represent the winds from that direction.

26.7.2 Surface Roughness Categories A ground surface roughness within each 45 degree sector shall be determined for a distance upwind of the site, as defined in Section 26.7.3, from the categories defined in the following text, for the purpose of assigning an exposure category as defined in Section 26.7.3.

Surface Roughness B. Urban and suburban areas, wooded areas, or other terrain with numerous, closely spaced obstructions that have the size of single-family dwellings or larger.

Surface Roughness C. Open terrain with scattered obstructions that have heights generally less than 30 ft (9.1 m). This category includes flat, open country and grasslands.

Surface Roughness D. Flat, unobstructed areas and water surfaces. This category includes smooth mud flats, salt flats, and unbroken ice.

26.7.3 Exposure Categories

Exposure B. For buildings or other structures with a mean roof height less than or equal to 30 ft (9.1 m), Exposure B shall apply where the ground surface roughness, as defined by Surface Roughness B, prevails in the upwind direction for a distance greater than 1,500 ft (457 m). For buildings or other structures with a mean roof height greater than 30 ft (9.1 m), Exposure B shall apply where Surface Roughness B prevails in the upwind direction for a distance greater than 2,600 ft (792 m) or 20 times the height of the building or structure, whichever is greater.

@seismicisolation

Exposure C. Exposure C shall apply for all cases where Exposure B or D does not apply.

Exposure D. Exposure D shall apply where the ground surface roughness, as defined by Surface Roughness D, prevails in the upwind direction for a distance greater than 5,000 ft (1,524 m) or 20 times the building or structure height, whichever is greater. Exposure D shall also apply where the ground surface roughness immediately upwind of the site is B or C, and the building or structure is within a distance of 600 ft (183 m) or 20 times the building or structure height, whichever is greater, from an Exposure D condition as defined in the previous sentence.

For a building or structure located in the transition zone between exposure categories, the category resulting in the largest wind forces shall be used.

EXCEPTION: An intermediate exposure between the preceding categories is permitted in a transition zone, provided it is determined by a rational analysis method defined in the recognized literature.

26.7.4 Exposure Requirements

26.7.4.1 Directional Procedure (Chapter 27) For each wind direction considered, wind loads for the design of the MWFRS of enclosed and partially enclosed buildings using the Directional Procedure of Chapter 27 shall be based on the exposures as defined in Section 26.7.3. Wind loads for the design of open buildings with monoslope, pitched, or troughed free roofs shall be based on the exposures, as defined in Section 26.7.3, resulting in the highest wind loads for any wind direction at the site.

26.7.4.2 Envelope Procedure (Chapter 28) Wind loads for the design of the MWFRS for all low-rise buildings designed using the Envelope Procedure of Chapter 28 shall be based on the exposure category resulting in the highest wind loads for any wind direction at the site.

26.7.4.3 Directional Procedure for Building Appurtenances and Other Structures (Chapter 29) Wind loads for the design of building appurtenances (such as rooftop structures and equipment) and other structures (such as solid freestanding walls and freestanding signs, chimneys, tanks, open signs, single-plane open frames, and trussed towers) as specified in Chapter 29 shall be based on the appropriate exposure for each wind direction considered.

26.7.4.4 Components and Cladding (Chapter 30) Design wind pressures for C&C shall be based on the exposure category resulting in the highest wind loads for any wind direction at the site.

26.8 TOPOGRAPHIC EFFECTS

26.8.1 Wind Speed-Up over Hills, Ridges, and Escarpments Wind speed-up effects at isolated hills, ridges, and escarpments constituting abrupt changes in the general topography, located in any exposure category, shall be included in the determination of the wind loads when site conditions and locations of buildings and other structures meet all the following conditions:

1. The building or other structure is located as shown in Figure 26.8-1 in the upper one-half of a hill or ridge or near the crest of an escarpment.
2. $H/L_h \geq 0.2$.
3. H is greater than or equal to 15 ft (4.5 m) for Exposures C and D and 60 ft (18 m) for Exposures B.

26.8.2 Topographic Factor The wind speed-up effect shall be included in the calculation of design wind loads by using the factor K_{zt}:

$$K_{zt} = (1 + K_1 K_2 K_3)^2 \qquad (26.8\text{-}1)$$

where K_1, K_2, and K_3 are given in Figure 26.8-1. The values for K_2 and K_3 shall not be less than 0. The equations for K_1, K_2, and K_3 may be used instead of using the tabular values when increased accuracy in determining K_{zt} is required. For $H/L_h > 0.5$, assume that $H/L_h = 0.5$ for evaluating K_1 and substitute $2H$ for L_h for evaluating K_2 and K_3.

If site conditions and locations of buildings and other structures do not meet all the conditions specified in Section 26.8.1, then $K_{zt} = 1.0$.

26.9 GROUND ELEVATION FACTOR

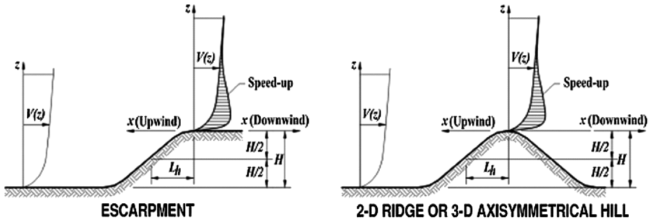
The ground elevation factor to adjust for air density, K_e, shall be determined in accordance with Table 26.9-1. It is permitted to take $K_e = 1$ for all elevations.

Table 26.9-1. Ground Elevation Factor, K_e.

Ground Elevation above Sea Level		Ground Elevation Factor, K_e
ft	m	
<0	<0	See note 2
0	0	1.00
1,000	305	0.96
2,000	610	0.93
3,000	914	0.90
4,000	1,219	0.86
5,000	1,524	0.83
6,000	1,829	0.80
>6,000	>1,829	See note 2

Notes:

1. Conservative approximation $K_e = 1.00$ is permitted in all cases.
2. Factor K_e shall be determined from Table 26.9-1 using interpolation or from the following formula for all elevations: $K_e = e^{-0.0000362 z_e}$ (z_e= ground elevation above sea level, ft); or $K_e = e^{-0.000119 z_e}$ (z_e= ground elevation above sea level, m).
3. K_e is permitted to be taken as 1.00 in all cases.



26.10 VELOCITY PRESSURE

26.10.1 Velocity Pressure Exposure Coefficient Based on the exposure category determined in Section 26.7.3, a velocity pressure exposure coefficient, K_z or K_h, as applicable, shall be determined from Table 26.10-1. For a site located in a transition zone between exposure categories that is near to a change in ground surface roughness, intermediate values of K_z or K_h, between those shown in Table 26.10-1 are permitted provided they are determined by a rational analysis method defined in the recognized literature.

26.10.2 Velocity Pressure Velocity pressure, q_z, evaluated at height z above ground shall be calculated by the following equation:

@seismicisolation
@seismicisolation

[a]For values of H / L_h, x / L_h, and z / L_h other than those shown, linear interpolation is permitted.

[b]For $H / L_h > 0.5$, assume that $H / L_h = 0.5$ for evaluating K_1 and substitute $2H$ for L_h for evaluating K_2 and K_3.

[c]Multipliers are based on the assumption that wind approaches the hill or escarpment along th direction of maximum slope.e

[d]Multipliers shall be used for any exposure.

Notation

H = Height of hill or escarpment relative to the upwind terrain, ft (m);
K_1 = Factor to account for shape of topographic feature and maximum speed-up effect;
K_2 = Factor to account for reduction in speed-up with distance upwind or downwind of crest;
K_3 = Factor to account for reduction in speed-up with height above local terrain;
L_h = Distance upwind of crest to where the difference in ground elevation is half the height of hill or escarpment, ft (m);
x = Distance (upwind or downwind) from the crest to the site of the building or other structure, ft (m);
z = Height above ground surface at the site of the building or other structure, ft (m);
μ = Horizontal attenuation factor;
γ = Height attenuation factor.

Equations

$K_{zt} = (1+K_1K_2K_3)^2$

K_1 = Determined from table above

$K_2 = (1-|x|/\mu L_h)$

$$K_3 = e^{-\gamma z/L_h}$$

Parameters for Speed-Up over Hills and Escarpments

Hill Shape	$K_1 / (H / L_h)$ Exposure B	C	D	γ	μ Upwind of Crest	Downwind of Crest
2D ridges (or valleys with negative H in $K_1 / (H/L_h)$	1.30	1.45	1.55	3	1.5	1.5
2D escarpments	0.75	0.85	0.95	2.5	1.5	4

Figure 26.8-1. Topographic factor, K_{zt}.

@seismicisolation

$$q_z = 0.00256 K_z K_{zt} K_e V^2 (\text{lb/ft}^2);\ V, \text{mi/h} \qquad (26.10\text{-}1)$$

$$q_z = 0.613 K_z K_{zt} K_e V^2 (\text{N/m}^2);\ V, \text{m/s} \qquad (26.10\text{-}1.\text{SI})$$

where

K_z = Velocity pressure exposure coefficient, see Section 26.10.1;
K_{zt} = Topographic factor, see Section 26.8.2;
K_e = Ground elevation factor, see Section 26.9;
V = Basic wind speed, see Section 26.5; and
q_z = Velocity pressure at height z.

The velocity pressure at mean roof height is computed as $q_h = q_z$ evaluated from Equation (26.10-1) using K_z at mean roof height h.

The basic wind speed, V, used in determination of design wind loads on rooftop structures, rooftop equipment, and other building appurtenances shall consider the Risk Category equal to the greater of the following:

1. Risk category for the building on which the equipment or appurtenance is located, or
2. Risk category for any building or other structure to which the equipment or appurtenance provides a necessary service.

26.11 GUST EFFECTS

26.11.1 Gust-Effect Factor The gust-effect factor for a rigid building or other structure is permitted to be taken as 0.85.

26.11.2 Frequency Determination To determine whether a building or other structure is rigid or flexible as defined in Section 26.2, the fundamental natural frequency, n_1, shall be established using the structural properties and deformational characteristics of the resisting elements in a properly substantiated analysis. Low-rise buildings, as defined in Section 26.2, are permitted to be considered rigid.

26.11.2.1 Limitations for Approximate Natural Frequency As an alternative to performing an analysis to determine n_1, the approximate building natural frequency, n_a, shall be permitted to be calculated in accordance with Section 26.11.3 for structural steel, concrete, or masonry buildings meeting the following requirements:

1. The building height is less than or equal to 300 ft (91 m).
2. The building height is less than four times its effective length, L_{eff}.

The effective length, L_{eff}, in the direction under consideration shall be determined from the following equation:

$$L_{\text{eff}} = \frac{\sum_{i=1}^{n} h_i L_i}{\sum_{i=1}^{n} h_i} \qquad (26.11\text{-}1)$$

The summations are over the height of the building, where h_i is the height above grade of level i, and L_i is the building length at level i parallel to the wind direction.

26.11.3 Approximate Natural Frequency The approximate lower bound natural frequency (n_a), in Hz, of concrete or structural steel buildings meeting the conditions of Section 26.11.2.1 is permitted to be determined from one of the following equations.

For structural steel moment-resisting frame buildings,

$$n_a = 22.2/h^{0.8} \qquad (26.11\text{-}2)$$

$$n_a = 8.58/h^{0.8} \qquad (26.11\text{-}2.\text{SI})$$

For concrete moment-resisting frame buildings,

$$n_a = 43.5/h^{0.9} \qquad (26.11\text{-}3)$$

$$n_a = 14.93/h^{0.9} \qquad (26.11\text{-}3.\text{SI})$$

Table 26.10-1. Velocity Pressure Exposure Coefficients, K_h and K_z.

Height above Ground Level, z or h		Exposure		
ft	m	B	C	D
0–15	0–4.6	0.57 (0.70)*	0.85	1.03
20	6.1	0.62 (0.70)*	0.90	1.08
25	7.6	0.66 (0.70)*	0.94	1.12
30	9.1	0.70	0.98	1.16
40	12.2	0.74	1.04	1.22
50	15.2	0.79	1.09	1.27
60	18.3	0.83	1.13	1.31
70	21.3	0.86	1.17	1.34
80	24.4	0.90	1.21	1.38

180	54.9	1.11	1.41	1.58
200	61.0	1.14	1.44	1.61
250	76.2	1.21	1.51	1.68
300	91.4	1.27	1.57	1.73
350	106.7	1.33	1.62	1.78
400	121.9	1.38	1.66	1.82
450	137.2	1.42	1.70	1.86
500	152.4	1.46	1.74	1.89

*Use 0.70 in Chapter 28, Exposure B, when $z < 30$ ft (9.1 m).

Notes:

1. Velocity pressure exposure coefficient K_z may be determined from the following formula:

For $z < 15$ ft	$K_z = 2.41\,(15/z_g)^{2/\alpha}$
For $z < 4.6$ m	$K_z = 2.41\,(4.6/z_g)^{2/\alpha}$
For 15 ft (4.6 m) $\le z \le z_g$	$K_z = 2.41\,(z/z_g)^{2/\alpha}$
For $z_g < z \le$ 3,280 ft (1,000 m)	$K_z = 2.41$

2. α and z_g are tabulated in Table 26.11-1.
3. Linear interpolation for intermediate values of height z is acceptable.
4. Exposure categories are defined in Section 26.7.

@seismicisolation

For structural steel and concrete buildings with other lateral-force-resisting systems,

$$n_a = 75/h \tag{26.11-4}$$

$$n_a = 22.86/h \tag{26.11-4.SI}$$

For concrete or masonry shear wall buildings, it is also permitted to use

$$n_a = 385(C_w)^{0.5}/h \tag{26.11-5}$$

$$n_a = 117.3(C_w)^{0.5}/h \tag{26.11-5.SI}$$

where

$$C_w = \frac{100}{A_B}\sum_{i=1}^{n}\left(\frac{h}{h_i}\right)^2 \frac{A_i}{\left[1+0.83\left(\frac{h_i}{D_i}\right)^2\right]}$$

where

h = Mean roof height, ft (m);
n = Number of shear walls in the building effective in resisting lateral forces in the direction under consideration;
A_B = Base area of the building, ft^2 (m^2);
A_i = Horizontal cross-sectional area of shear wall i, ft^2 (m^2);
D_i = Length of shear wall i, ft (m); and
h_i = Height of shear wall i, ft (m).

26.11.4 Rigid Buildings or Other Structures For rigid buildings or other structures as defined in Section 26.2, the gust-effect factor shall be taken as 0.85 or calculated by this formula:

$$G = 0.925\left(\frac{1+1.7g_Q I_{\bar{z}} Q}{1+1.7g_v I_{\bar{z}}}\right) \tag{26.11-6}$$

$$I_{\bar{z}} = c\left(\frac{33}{\bar{z}}\right)^{1/6} \tag{26.11-7}$$

$$I_{\bar{z}} = c\left(\frac{10}{\bar{z}}\right)^{1/6} \tag{26.11-7.SI}$$

where $I_{\bar{z}}$ is the intensity of turbulence at height $\bar{z}$, and $\bar{z}$ is the equivalent height of the building or structure defined as $0.6h$, but not less than z_{min}, for all building or structure heights h. z_{min} and c are listed for each exposure in Table 26.11-1; g_Q and g_v shall be taken as 3.4. The background response Q is given by

$$Q = \sqrt{\frac{1}{1+0.63\left(\frac{B+h}{L_{\bar{z}}}\right)^{0.63}}} \tag{26.11-8}$$

where B and h are defined in Section 26.3, and $L_{\bar{z}}$ is the integral length scale of turbulence at the equivalent height given by

$$L_{\bar{z}} = \ell\left(\frac{\bar{z}}{33}\right)^{\bar{\varepsilon}} \tag{26.11-9}$$

$$L_{\bar{z}} = \ell\left(\frac{\bar{z}}{10}\right)^{\bar{\varepsilon}} \tag{26.11-9.SI}$$

in which ℓ and $\bar{\varepsilon}$ are constants listed in Table 26.11-1.

26.11.5 Flexible Buildings or Other Structures For flexible buildings or other structures as defined in Section 26.2, the gust-effect factor shall be calculated by

$$G_f = 0.925\left(\frac{1+1.7I_{\bar{z}}\sqrt{g_Q^2Q^2+g_R^2R^2}}{1+1.7g_vI_{\bar{z}}}\right) \tag{26.11-10}$$

The background peak factors g_Q and g_v shall be taken as 3.4, and the resonant peak factor g_R is

$$g_R = \sqrt{2\ln(3{,}600n_1)} + \frac{0.577}{\sqrt{2\ln(3{,}600n_1)}} \tag{26.11-11}$$

The background response factor, Q, and the intensity of turbulence at height z, I_z, are defined in Section 26.11.4. The resonant response factor is

$$R = \sqrt{\frac{1}{\beta}R_nR_hR_B(0.53+0.47R_L)} \tag{26.11-12}$$

where n_1 is the fundamental natural frequency, and β is the damping ratio, fraction of critical (e.g., for 2% use 0.02 in the equation).

Table 26.11-1. Terrain Exposure Constants.

Customary Units

Exposure	α	z_g (ft)	$\hat{\alpha}$	$\hat{b}$	$\bar{\alpha}$	$\bar{b}$	c	l (ft)	$\bar{\varepsilon}$	z_{min} (ft)*
B	7.5	3,280	1/7.5	0.84	1/4.5	0.47	0.30	320	1/3.0	30
C	9.8	2,460	1/9.8	1.00	1/6.4	0.66	0.20	500	1/5.0	15
D	11.5	1,935	1/11.5	1.09	1/8.0	0.78	0.15	650	1/8.0	7

SI Units

Exposure	α	z_g (m)	$\hat{\alpha}$	$\hat{b}$	$\bar{\alpha}$	$\bar{b}$	c	l (m)	$\bar{\varepsilon}$	z_{min} (m)*
B	7.5	1,000	1/7.5	0.84	1/4.5	0.47	0.30	97.54	1/3.0	9.14
C	9.8	750	1/9.8	1.00	1/6.4	0.66	0.20	152.40	1/5.0	4.57
D	11.5	590	1/11.5	1.09	1/8.0	0.78	0.15	198.12	1/8.0	2.13

* z_{min} = Minimum height used to ensure that the equivalent height $\bar{z}$ is the greater of $0.6h$ or z_{min}. For buildings or other structures with $h \le z_{min}$, $\bar{z}$ shall be taken as z_{min}.

@seismicisolation

The power spectral density of turbulence at the equivalent height of the structure $\bar{z}$, evaluated at the structure's natural reduced frequency, N_1, is

$$R_n = \frac{7.47N_1}{(1+10.3N_1)^{5/3}} \tag{26.11-13}$$

$$N_1 = \frac{n_1 L_{\bar{z}}}{\overline{V}_{\bar{z}}} \tag{26.11-14}$$

where $L_{\bar{z}}$ is defined in Equation (26.11-9).

The size effect factors related to the height, breadth, and depth of the building are

$$\begin{aligned} R_h &= \frac{1}{\eta_h} - \frac{1}{2\eta_h^2}\left(1-e^{-2\eta_h}\right) \\ R_B &= \frac{1}{\eta_B} - \frac{1}{2\eta_B^2}\left(1-e^{-2\eta_B}\right) \\ R_L &= \frac{1}{\eta_L} - \frac{1}{2\eta_L^2}\left(1-e^{-2\eta_L}\right) \end{aligned} \tag{26.11-15a}$$

where the turbulent coherence (correlation) factors in the corresponding directions, evaluated at the natural reduced frequency, are

$$\begin{aligned} \eta_h &= 4.6n_1 h/\overline{V}_z \\ \eta_B &= 4.6n_1 B/\overline{V}_z \\ \eta_L &= 15.4n_1 L/\overline{V}_z \end{aligned} \tag{26.11-15b}$$

The mean hourly wind speed (in ft/s or m/s) at the equivalent structure height, $\bar{z}$, is

$$\overline{V}_{\bar{z}} = \overline{b}\left(\frac{\bar{z}}{33}\right)^{\overline{\alpha}}\left(\frac{88}{60}\right)V \tag{26.11-16}$$

$$\overline{V}_{\bar{z}} = \overline{b}\left(\frac{\bar{z}}{10}\right)^{\overline{\alpha}} V \tag{26.11-16.SI}$$

where $\overline{b}$ and $\overline{\alpha}$ are constants listed in Table 26.11-1, $\bar{z}$ is obtained from Section 26.11.4, and V is the basic wind speed, mi/h (m/s).

26.11.6 Rational Analysis In lieu of the procedure defined in Sections 26.11.4 and 26.11.5, determination of the gust-effect factor by any rational analysis defined in the recognized literature is permitted.

26.11.7 Limitations Where combined gust-effect factors and pressure coefficients (GC_p), (GC_{pi}), and (GC_{pf}) are given in figures and tables, the gust-effect factor shall not be determined separately.

26.12 ENCLOSURE CLASSIFICATION

26.12.1 General For the purpose of determining internal pressure coefficients, buildings and other structures for which internal pressure coefficients (GC_{pi}) apply shall be classified as enclosed, partially enclosed, partially open, or open, as defined in Section 26.2. If a building or other structure satisfies both the "open" and "partially enclosed" enclosure classification definitions, it shall be classified as a "partially open" building or other structure.

26.12.2 Openings A determination shall be made of the amount of openings in the building envelope for use in determining the enclosure classification. To make this determination, each building wall shall be assumed as the windward wall for consideration of the amount of openings present with respect to the remaining building envelope.

26.12.3 Protection of Glazed Openings Glazed openings in Risk Category II, III, or IV buildings located in hurricane-prone regions shall be protected as specified in this section.

26.12.3.1 Wind-Borne Debris Regions Glazed openings shall be protected in accordance with Section 26.12.3.2 in the following locations:

1. Within 1 mi (1.6 km) of the mean high water line where an Exposure D condition exists upwind of the waterline and the basic wind speed is equal to or greater than 130 mi/h (58 m/s), or
2. In areas where the basic wind speed is equal to or greater than 140 mi/h (63 m/s).

For Risk Category II buildings and other structures and Risk Category III buildings and other structures, except health care facilities, the wind-borne debris region shall be based on Figure 26.5-1B. For Risk Category III health care facilities, the wind-borne debris region shall be based on Figure 26.5-1C. For Risk Category IV buildings and structures, the wind-borne debris region shall be based on Figure 26.5-1D. Risk categories shall be determined in accordance with Section 1.5.

EXCEPTION: Glazing located more than 60 ft (18.3 m) above the ground and more than 30 ft (9.2 m) above aggregate-surfaced roofs, including roofs with gravel or stone ballast, located within 1,500 ft (458 m) of the building shall be permitted to be unprotected.

26.12.3.2 Protection Requirements for Glazed Openings Glazing in buildings requiring protection shall be impact resistant or be protected with an impact-protective system.

Impact-protective systems and impact-resistant glazing shall be subjected to missile test and cyclic pressure differential tests in accordance with ASTM E1996 as applicable. Testing to demonstrate compliance with ASTM E1996 shall be in accordance with ASTM E1886. Impact-resistant glazing and impact-protective systems shall comply with the pass/fail criteria of Section 7 of ASTM E1996 based on the missile required by Table 3 or Table 4 of ASTM E1996. Glazing in sectional doors, rolling doors, and flexible doors shall be subjected to missile tests and cyclic pressure differential tests in accordance with ANSI/DASMA 115 as applicable.

Glazing and impact-protective systems in buildings and other structures classified as Risk Category IV in accordance with Section 1.5 shall comply with the "enhanced protection" requirements of Table 3 of ASTM E1996. Glazing and impact-protective systems in all other buildings covered by Section 26.12.3.1 shall comply with the "basic protection" requirements of Table 3 of ASTM E1996.

EXCEPTION: When approved, other testing methods and/or performance criteria shall be permitted to be used to demonstrate compliance with all provisions of this section.

26.13 INTERNAL PRESSURE COEFFICIENTS

Internal pressure coefficients (GC_{pi}) shall be determined from Table 26.13-1 based on building enclosure classifications determined from Section 26.12.

26.13.1 Reduction Factor for Large-Volume Buildings, R_i For a partially enclosed building containing a single,

@seismicisolation

Table 26.13-1. Main Wind Force Resisting System and Components and Cladding (All Heights): Internal Pressure Coefficient, (GC_{pi}), for Enclosed, Partially Enclosed, Partially Open, and Open Buildings (Walls and Roof).

Enclosure Classification	Criteria for Enclosure Classification	Internal Pressure	Internal Pressure Coefficient (GC_{pi})
Enclosed buildings	A_o is less than the smaller of $0.01A_g$ or 4 ft^2 (0.37 m^2), and $A_{oi}/A_{gi} \le 0.2$	Moderate	+0.18 −0.18
Partially enclosed buildings	$A_o > 1.1A_{oi}$, and $A_o >$ the lesser of $0.01A_g$ or 4 ft^2 (0.37 m^2), and $A_{oi}/A_{gi} \le 0.2$	High	+0.55 −0.55
Partially open buildings	A building that does not comply with Enclosed, Partially Enclosed, or Open classifications	Moderate	+0.18 −0.18
Open buildings	Each wall is at least 80% open	Negligible	0.00

Notes:

1. Plus and minus signs signify pressures acting toward and away from the internal surfaces, respectively.
2. Values of (GC_{pi}) shall be used with q_z or q_h as specified.
3. Two cases shall be considered to determine the critical load requirements for the appropriate condition:
   (a) A positive value of (GC_{pi}) applied to all internal surfaces, or
   (b) A negative value of (GC_{pi}) applied to all internal surfaces.

unpartitioned large volume, the internal pressure coefficient, (GC_{pi}), shall be multiplied by the reduction factor, R_i:

$$R_i = 1.0 \quad \text{or} \quad R_i = 0.5\left(1 + \frac{1}{\sqrt{1 + \frac{V_i}{22{,}800A_{og}}}}\right) < 1.0 \quad (26.13\text{-}1)$$

where A_{og} is the total area of openings in the building envelope [walls and roof (ft^2)], and V_i is the unpartitioned internal volume (ft^3).

26.14 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

This section lists the consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

CHAPTER 27
WIND LOADS ON BUILDINGS: MAIN WIND FORCE RESISTING SYSTEM (DIRECTIONAL PROCEDURE)

27.1 SCOPE

27.1.1 Building Types This chapter applies to the determination of Main Wind Force Resisting System (MWFRS) wind loads on enclosed, partially enclosed, partially open, and open buildings of all heights using the Directional Procedure, in which it is necessary to separate applied wind loads onto the windward, leeward, and sidewalls of the building to properly assess the internal forces in the MWFRS members.

27.1.2 Conditions A building that has design wind loads determined in accordance with this chapter shall comply with both of the following conditions:

1. The building is a regular-shaped building as defined in Section 26.2, and
2. The building does not have response characteristics that make it subject to across-wind loading, vortex shedding, or instability caused by galloping or flutter; nor does it have a site location for which channeling effects or buffeting, in the wake of upwind obstructions, warrant special consideration.

27.1.3 Limitations The provisions of this chapter take into consideration the load magnification effect caused by gusts, in resonance with along-wind vibrations of flexible buildings. Buildings that do not meet the requirements of Section 27.1.2 or that have unusual shapes or response characteristics shall be designed using recognized literature, documenting such wind load effects, or shall use the Wind Tunnel Procedure specified in Chapter 31.

27.1.4 Shielding There shall be no reductions in velocity pressure caused by apparent shielding afforded by buildings and other structures or terrain features.

27.1.5 Minimum Design Wind Loads The wind pressure to be used in the design of the MWFRS for an enclosed, or partially enclosed, building shall not be less than 16 lb/ft^2 (0.77 kN/m^2) multiplied by the wall area of the building, and 8 lb/ft^2 (0.38 kN/m^2) multiplied by the roof area of the building, projected onto a vertical plane normal to the assumed wind direction. Wall and roof loads shall be applied simultaneously. The design wind force for open buildings shall be not less than 16 lb/ft^2 (0.77 kN/m^2) multiplied by the area, A_f.

27.2 GENERAL REQUIREMENTS

User Note: Use Chapter 27 to determine wind pressures on the MWFRS of buildings with any general plan shape, building height, or roof geometry that matches the figures provided. These provisions use the traditional "all heights" method (Directional Procedure) by calculating wind pressures using *specific wind pressure equations* applicable to each building surface.

The steps to determine the wind loads on the MWFRS for enclosed, partially enclosed, partially open, and open buildings of all heights are provided in Table 27.2-1.

27.2.1 Wind Load Parameters Specified in Chapter 26 The following wind load parameters shall be determined in accordance with Chapter 26:

- Basic wind speed, V (Section 26.5);
- Wind directionality factor, K_d (Section 26.6);
- Exposure category (Section 26.7);
- Topographic factor, K_{zt} (Section 26.8);
- Ground elevation factor, K_e (Section 26.9);
- Gust-effect factor (Section 26.11);
- Enclosure classification (Section 26.12); and
- Internal pressure coefficient, (GC_{pi}) (Section 26.13).

27.3 WIND LOADS: MAIN WIND FORCE RESISTING SYSTEM

27.3.1 Enclosed, Partially Enclosed, and Partially Open Rigid and Flexible Buildings Design wind pressures for the MWFRS of buildings of all heights in lb/ft^2 (N/m^2), shall be determined by the following equation:

$$p = qK_dGC_p - q_iK_d(GC_{pi}) \qquad (27.3\text{-}1)$$

where

$q = q_z$ For windward walls evaluated at height z above the ground;
$q = q_h$ For leeward walls, sidewalls, and roofs evaluated at height h;

@seismicisolation

Table 27.2-1. Steps to Determine MWFRS Wind Loads for Enclosed, Partially Enclosed, Partially Open, and Open Buildings of All Heights.

Step 1: Determine Risk Category of building; see Table 1.5-1.
Step 2: Determine the basic wind speed, V, for the applicable risk category; see Figure 26.5-1.
Step 3: Determine wind load parameters:
- Wind directionality factor, K_d; see Section 26.6 and Table 26.6-1.
- Exposure category; see Section 26.7.
- Topographic factor, K_{zt}; see Section 26.8 and table in Figure 26.8-1.
- Ground elevation factor, K_e; see Section 26.9.
- Gust-effect factor, G or G_f; see Section 26.11.
- Enclosure classification; see Section 26.12.
- Internal pressure coefficient, (GC_{pi}); see Section 26.13 and Table 26.13-1.

Step 4: Determine velocity pressure exposure coefficient, K_z or K_h; see Table 26.10-1.
Step 5: Determine velocity pressure q_z or q_h, Equation (26.10-1).
Step 6: Determine external pressure coefficient, C_p or C_N:
- Figure 27.3-1 for walls and flat, gable, hip, monoslope, or mansard roofs;
- Figure 27.3-2 for domed roofs;
- Figure 27.3-3 for arched roofs;
- Figure 27.3-4 for monoslope roof, open building;
- Figure 27.3-5 for pitched roof, open building;
- Figure 27.3-6 for troughed roof, open building; and
- Figure 27.3-7 for along-ridge/valley wind load case for monoslope, pitched, or troughed roof, open building.

Step 7: Calculate wind pressure, p, on each building surface:
- Equation (27.3-1) for rigid and flexible buildings, and
- Equation (27.3-2) for open buildings.

Step 8: Evaluate design wind load cases according to Section 27.3.5 and Figure 27.3-8.

$q_i = q_h$ For windward walls, sidewalls, leeward walls, and roofs of enclosed buildings, partially open buildings, and for negative internal pressure evaluation in partially enclosed buildings;

$q_i = q_z$ For positive internal pressure evaluation in partially enclosed buildings, where height z is defined as the level of the highest opening in the building that could affect the positive internal pressure; For buildings sited in wind-borne debris regions, the enclosure classification with respect to glazed openings shall be in accordance with Section 26.12.3, and for positive internal pressure evaluation, q_i may conservatively be evaluated at height $h(q_i = q_h)$;

K_d = Wind directionality factor (see Section 26.6);

G = Gust-effect factor (see Section 26.11); For flexible buildings, G_f, determined in accordance with Section 26.11.5, shall be substituted for G;

C_p = External pressure coefficient from Figures 27.3-1, 27.3-2, and 27.3-3; and

(GC_{pi}) = Internal pressure coefficient from Table 26.13-1.

Both q and q_i shall be evaluated using exposure defined in Section 26.7.3. Pressure shall be applied simultaneously on windward and leeward walls and on roof surfaces, as defined in Figures 27.3-1, 27.3-2, and 27.3-3.

27.3.1.1 Elevated Buildings The MWFRS loads for rigid or flexible elevated buildings meeting both of the following geometric limitations, for any principal wind direction, shall be determined in accordance with this section for that principal direction.

1. The sum of the cross-sectional areas of the supporting structural elements and any enclosed or partially enclosed spaces beneath the building, as seen in a horizontal cross-section through the space under the building, does not exceed the indicated percentage of the plan cross-sectional area of the aforementioned building for the indicated L/B ratio (linear interpolation is allowed):

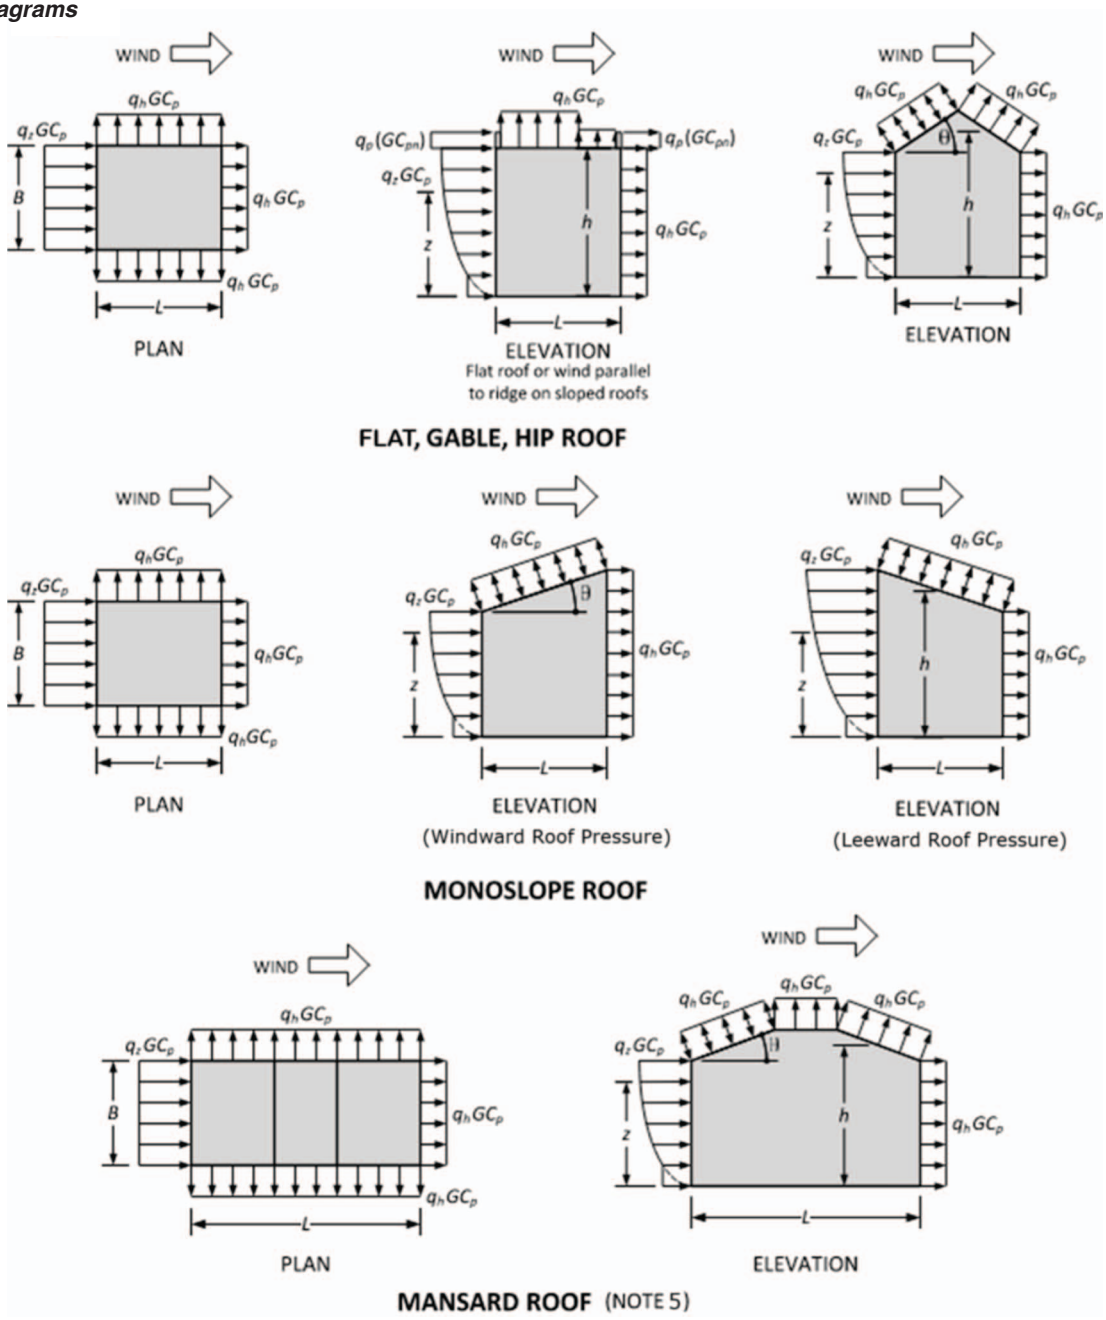
   L/B Ratio Percentage of Plan Area of Building Blocked by Elements or Enclosures Beneath the Building

L/B	Plan Area Blocked
<2.5	50%
3.0	45%
3.5	40%
4.0	36%
4.5	33%
5.0	30%

2. The sum of the areas of the supporting structural elements and any enclosed, partially enclosed or partially open spaces, as projected onto a vertical plane normal to the wind direction, does not exceed 75% of the projected area outlined by the height of these elements and the projected width of the building above.

For buildings that do not meet both of these criteria for a particular principal wind direction, wind loads for that direction shall be determined using Section 27.3.1. The wind loads on the portion of the building consisting of the structural elements, and enclosed or partially enclosed spaces beneath the elevated building, shall be calculated assuming the wind is unable to pass beneath the building and that portion of the building has no openings.

For buildings that meet both of these criteria for a particular principal direction, the overall lateral MWFRS loads shall include the combined effects of wind loads determined for the elevated building (Section 27.3.1.1.1) and for the supporting structural elements including any enclosed, partially enclosed, or partially open spaces below the elevated building (Section 27.3.1.1.2). MWFRS wind loads for the bottom surface of the elevated building shall not be used to reduce the effects of wind loads on overturning moments.



27.3.1.1.1 Elevated Building Loads Wind loads on the roof and walls of the elevated building shall be calculated using the methods and pressure coefficients defined in Section 27.3.1.

27.3.1.1.2 Lateral Loads on Elements Below the Elevated Building Lateral wind loads on elements below the elevated building shall be calculated using

1. Projected areas of all the structural elements below the elevated building perpendicular to the wind direction being considered, neglecting potential shielding;

@seismicisolation

Diagrams

Notation

B = Horizontal dimension of building, ft (m), measured normal to wind direction.

L = Horizontal dimension of building, ft (m), measured parallel to wind direction.

h = Mean roof height, ft (m), except that eave height shall be used for $\theta \le 10$ degrees.

z = Height above ground, ft (m).

G = Gust-effect factor.

q_z, q_h, q_p = Velocity pressure, lb/ft^2 (N/m^2), evaluated at respective height.

θ = Angle of plane of roof from horizontal, degrees.

C_p = External pressure coefficient.

GC_{pn} = Combined net pressure coefficient for a parapet.

Figure 27.3-1. Main wind force resisting system: external pressure coefficients, C_p, for enclosed, partially enclosed, and partially open buildings—walls and roofs.

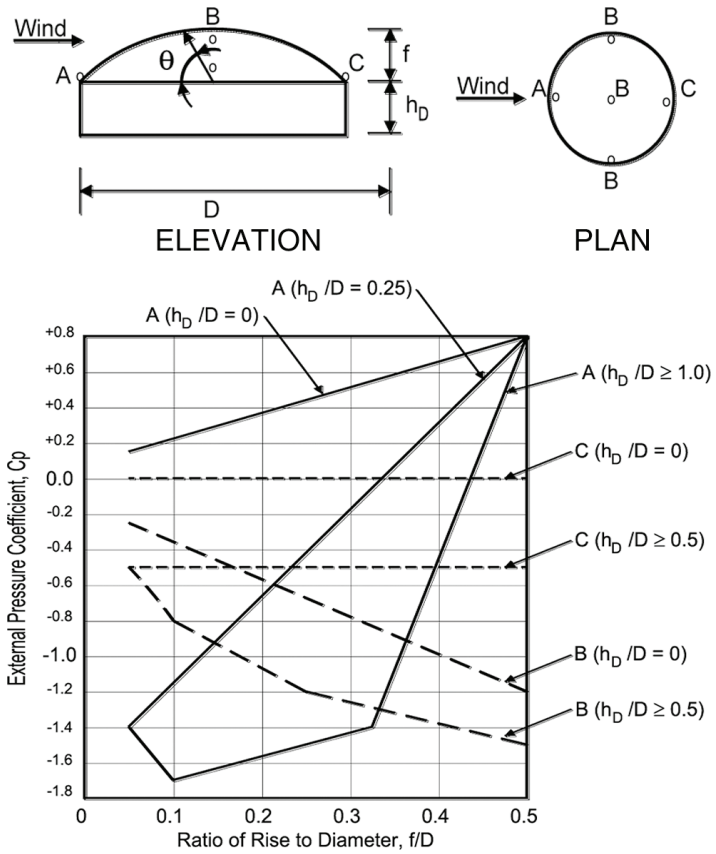
		$h/2$ to h	−0.9, −0.18
		h to $2h$	−0.5, −0.18
		$>2h$	−0.3, −0.18
	≥ 1.0	0 to $h/2$	−1.3[b], −0.18
		$>h/2$	−0.7, −0.18

[a]Value is provided for interpolation purposes.

[b]Value can be reduced linearly, with area over which it is applicable as follows:

Area, ft² (m²)	Reduction Factor
≤100 (9.3)	1.0
250 (23.2)	0.9
≥1,000 (92.9)	0.8

Notes:



1. Plus and minus signs signify pressures acting toward and away from the surfaces, respectively.
2. Linear interpolation is permitted for values of L/B, h/L, and θ, other than shown. Interpolation shall only be carried out between values of the same sign Where no value of the same sign is given, assume 0·0 for interpolation purposes·
3. Where two values of C_p are listed, this indicates that the windward roof slope is subjected to either positive or negative pressures and the roof structure shall be designed for both conditions. Interpolation for intermediate ratios of h/L shall only be carried out between C_p values of like sign.
4. Parapets are shown only on the flat roof elevation but may occur on any roof type shown.
5. For mansard roofs, the top horizontal surface and leeward inclined surface shall be treated as leeward surfaces according to the table
6. Except for MWFRSs at the roof consisting of moment-resisting frames, the total horizontal shear shall not be less than that determined by neglecting wind forces on roof surfaces

Figure 27.3-1 (*Continued*). Main wind force resisting system: external pressure coefficients, C_p, for enclosed, partially enclosed, and partially open buildings—walls and roofs.

@seismicisolation

Diagrams

External Pressure Coefficients for Domes with Circular Base

Notation

f = Dome rise, ft (m)

h_D = Height to base of dome, ft (m)

D = Diameter, ft (m)

θ = Angle of plane of roof from horizontal, degrees

Notes

1. Two load cases shall be considered:
   Case A: C_p values between A and B and between B and C shall be determined by linear interpolation along arcs on the dome parallel to the wind direction;
   Case B: C_p shall be the constant value of A for $\theta \le 25°$ and shall be determined by linear interpolation from 25 degrees to B and from B to C.
2. Values denote C_p to be used with $q_{(h_{D+f})}$, where h_{D+f} is the height at the top of the dome.
3. Plus and minus signs signify pressures acting toward and away from the surfaces, respectively.
4. C_p is constant on the dome surface for arcs of circles perpendicular to the wind direction; for example, the arc passing through $B - B - B$ and all arcs parallel to $B - B - B$
5. For values of h_D/D between those listed on the graph curves, linear interpolation shall be permitted.
6. $\theta = 0$ degrees on dome springline $\theta = 90$ degrees at dome center top point. f is measured from springline to top. ,
7. The total horizontal shear shall not be less than that determined by neglecting wind forces on roof surfaces.
8. For f/D values less than 0.05, use Figure 27.3-1.

Figure 27.3-2. Main wind force resisting system: external pressure coefficients, C_p, for enclosed, partially enclosed, and partially open buildings and structures—domed roofs with a circular base.

@seismicisolation

External Pressure Coefficient, C_p

Conditions	Rise-to-Span Ratio, r	C_p Windward Quarter	C_p Center Half	C_p Leeward Quarter
Roof on elevated structure	$0 < r < 0.2$	-0.9	$-0.7 - r$	-0.5
	$0.2 \le r < 0.3$	$1.5r - 0.3$ $6r - 2.1$	$-0.7 - r$	-0.5
	$0.3 \le r \le 0.6$	$2.75r - 0.7$	$-0.7 - r$	-0.5
Roof springing from ground level	$0 < r \le 0.6$	$1.4r$	$-0.7 - r$	-0.5

Notes

1. Values listed are for the determination of average loads on main wind-force resisting systems.
2. Plus and minus signs signify pressures acting toward and away from the surfaces, respectively.
3. For wind directed parallel to the axis of the arched roofs, use pressure coefficients from Figure 27.3-1, with wind directed parallel to ridge.
4. Where two values of C_p are listed, the roof is subjected to either positive or negative pressures and the roof structure shall be designed for both conditions.

Figure 27.3-3. Main wind force resisting system: external pressure coefficients, C_p, for enclosed, partially enclosed, and partially open buildings and structures—arched roofs.

2. Net force coefficient of 1.3 applied to the projected area of all the elements; and,
3. q_z where z is set equal to the height above grade of the bottom horizontal surface of the elevated portion of the building plus 25% of the distance from the bottom of the elevated portion of the building to the mean roof height.

27.3.1.1.3 External Loads on Horizontal Bottom Surfaces of the Elevated Building Vertical wind loads on the bottom surfaces of the elevated building shall be calculated using

1. Roof pressure coefficients for the wind direction "normal to the ridge for $\theta < 10°$ and parallel to ridge for all θ" provided in Figure 27.3-1. Negative roof pressure coefficients denote downward loading on the bottom floor assembly, while positive roof pressure coefficients denote upward loading.
2. Value of h, used to define the distance from the windward edge, shall be taken as the height of the top of the elements below the elevated building; and,
3. Velocity pressure, used to calculate external pressures on this floor, shall be q_z, where z is set equal to the height above grade of the bottom horizontal surface of the elevated portion of the building plus 25% of the distance from the bottom of the elevated portion of the building to the mean roof height.

27.3.2 Open Buildings with Monoslope, Pitched, or Troughed Free Roofs The net design pressure for the MWFRS of open buildings with monoslope, pitched, or troughed free roofs in lb/ft^2 (N/m^2), shall be determined by Equation (27.3-2):

$$p = q_h K_d G C_N \tag{27.3-2}$$

where

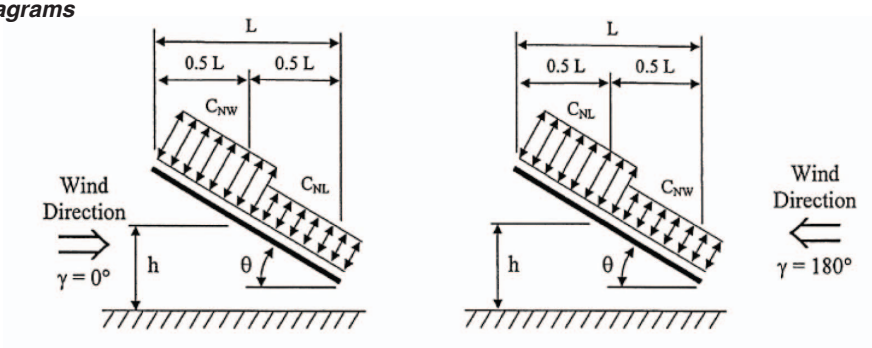
q_h = Velocity pressure evaluated at mean roof height, h, using the exposure as defined in Section 26.7.3 that results in the highest wind loads for any wind direction at the site;
K_d = Wind directionality factor (see Section 26.6);
G = Gust-effect factor from Section 26.11; and
C_N = Net pressure coefficient determined from Figures 27.3-4 through 27.3-7.

Net pressure coefficients, C_N, include contributions from top and bottom surfaces. All load cases shown for each roof angle shall be investigated. Plus and minus signs signify pressure acting toward and away from the top surface of the roof, respectively.

For free roofs with an angle of plane of roof from horizontal θ less than or equal to 5 degrees and containing fascia panels, the fascia panel shall be considered to be an inverted parapet. The contribution of loads on the fascia to the MWFRS loads shall be determined using Section 27.3.5, with q_p equal to q_h. For an open or partially enclosed building with transverse frames and a pitched roof ($\theta \le 45°$), an additional horizontal force in the longitudinal direction (parallel to the ridge) that acts in combination with the roof load calculated in Section 27.3.3 shall be determined in accordance with Section 28.3.5.

27.3.3 Roof Overhangs The positive external pressure on the bottom surface of windward roof overhangs shall be determined using $C_p = 0.8$ and combined with the top surface pressures determined using Figure 27.3-1.

27.3.4 Parapets The design wind pressure for the effect of parapets on MWFRS of rigid or flexible buildings in lb/ft^2 (N/m^2) shall be determined by Equation (27.3-3):



$$p_p = q_p K_d (GC_{pn}) \tag{27.3-3}$$

where

p_p = Combined net pressure on the parapet caused by the combination of the net pressures from the front and back parapet surfaces in which plus (and minus) signs signify net pressure acting toward (and away from) the front (exterior) side of the parapet;
q_p = Velocity pressure evaluated at the top of the parapet;
K_d = Wind directionality factor (see Section 26.6); and
(GC_{pn}) = Combined net pressure coefficient, which is $+1.5$ for windward parapet or -1.0 for leeward parapet.

@seismicisolation

Diagrams

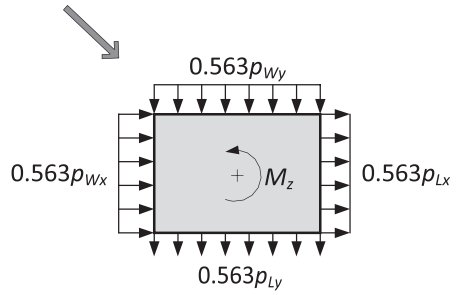
CASE 1

Full design pressure on the projected wall area perpendicular to each principal axis of the structure, considered separately along each principal axis. Full design pressure on side walls and roof areas for wind along each principal axis as specified in Figures 27.3-1 through 27.3-7. All pressures act simultaneously for each principal wind direction.

CASE 3

Wall pressures are 75% of Case 1. For roof pressures, see Note 2. All pressures act simultaneously.



$M_z = 0.75(p_{Wx} + p_{Lx})B_x e_x$ $\quad$ $M_z = 0.75(p_{Wy} + p_{Ly})B_y e_y$

$e_x = \pm 0.15B_x$ $\quad$ $e_y = \pm 0.15B_y$

CASE 2

Three-quarters of design wind pressure on the projected wall area perpendicular to each principal axis of the structure and sidewalls in conjunction with a torsional moment, considered separately along each principal direction. Roof pressures are 75% of Case 1. All pressures and torsion act simultaneously for each principal wind direction.

$M_z = 0.563(p_{Wx} + p_{Lx})B_x e_x + 0.563(p_{Wy} + p_{Ly})B_y e_y$

$e_x = \pm 0.15B_x$ $\quad$ $e_y = \pm 0.15B_y$

CASE 4

Wall pressures and torsional moment are 75% of Case 2 (wall pressures are 56.3% of Case 1). For roof pressures see Note 2. All pressures and torsion act simultaneously.

Notation

p_{Wx}, p_{Wy} = Windward wall design pressure acting in the x, y principal direction, respectively.
p_{Lx}, p_{Ly} = Leeward wall design pressure acting in the x, y principal direction, respectively.
B_x, B_y = Horizontal dimension of building normal to the wind in the x, y principal direction, respectively.
e_x, e_y = Eccentricity from the x, y principal axis of the structure, respectively; as shown for rigid buildings, or as defined by Equation (27.3-4) for flexible buildings. See also Note 4.
M_z = Torsional moment per unit height acting about a vertical axis of the building.

Notes

1. Diagrams show plan views of buildings.
2. Pressures on roof are not shown for clarity. For Cases 3 and 4 the resulting pressure on any roof area defined by the two principal wind directions of Cases 1 and 2 shall be 100% of the larger value of the roof pressures defined for Cases 1 and 2, respectively.
3. Pressures on sidewalls for Cases 1 and 2 are not shown for clarity and need not be considered at floors with rigid diaphragms continuous with the sidewalls.
4. M_z shall be applied on rigid diaphragms. On floors with semi-rigid or flexible diaphragms, or without diaphragms, it shall be permitted to apply M_z using an equivalent distributed pressure block on all walls receiving normal wind pressure, applied in the proportion specified for each wall in Figure 27.3-1, or using other rational methods.

Figure 27.3-8. Main wind force resisting system, design wind load cases.

@seismicisolation

27.3.5 Design Wind Load Cases The MWFRS of buildings of all heights, the wind loads of which have been determined under the provisions of this chapter, shall be designed for the wind load cases as defined in Figure 27.3-8.

EXCEPTION: Buildings meeting the requirements of Section D.1 of Appendix D need only be designed for Case 1 and Case 3 of Figure 27.3-8.

The eccentricity e for rigid buildings shall be measured from the geometric center of the building face and shall be considered for each principal axis (e_X,e_Y). The eccentricity e for flexible buildings shall be determined from the following equation and shall be considered for each principal axis (e_X,e_Y):

$$e = \frac{e_Q + 1.7 I_z \sqrt{(g_Q Q e_Q)^2 + (g_R R e_R)^2}}{1 + 1.7 I_z \sqrt{(g_Q Q)^2 + (g_R R)^2}} \qquad (27.3\text{-}4)$$

where

e_Q = Eccentricity e as determined for rigid buildings in Figure 27.3-8; and

e_R = Distance between the elastic shear center and center of mass of each floor, and I_z, g_Q, Q, g_R, and R shall be as defined in Section 26.11.

The sign of the eccentricity e shall be plus or minus, whichever causes the more severe load effect.

27.4 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

No consensus standards and other documents that shall be considered part of this standard are referenced in this chapter.

@seismicisolation

CHAPTER 28
WIND LOADS ON BUILDINGS: MAIN WIND FORCE RESISTING SYSTEM (ENVELOPE PROCEDURE)

28.1 SCOPE

28.1.1 Building Types This chapter applies to the determination of Main Wind Force Resisting System (MWFRS) wind loads, using the Envelope Procedure, on low-rise buildings as defined in Section 26.2.

28.1.2 Conditions The design wind loads determined in accordance with this section shall apply to buildings complying with all the following conditions:

1. Building is a regular-shaped building as defined in Section 26.2.
2. Building does not have response characteristics that make it subject to across-wind loading, vortex shedding, or instability caused by galloping or flutter, nor does it have a site location for which channeling effects or buffeting in the wake of upwind obstructions warrant special consideration.
3. Building does not have an arched, barrel, or unusually shaped roof.

28.1.3 Limitations The provisions of this chapter take into consideration mean and fluctuating loads caused by winds acting on rigid buildings. Buildings that do not meet the conditions of Section 28.1.2 shall be designed using appropriate procedures in Chapter 27, recognized literature documenting such wind load effects, or the Wind Tunnel Procedure specified in Chapter 31.

28.1.4 Shielding There shall be no reductions in velocity pressure caused by shielding that may be afforded by other buildings and other structures or terrain features.

User Note: Use Chapter 28 to determine the wind pressure on the MWFRS of *low-rise buildings* that have a flat, gable, or hip roof. These provisions use the Envelope Procedure by calculating wind pressures from the *specific equation* applicable to each building surface. For building shapes and heights for which these provisions are applicable, this method generally yields the lowest wind pressure of all the analytical methods specified in this standard.

28.2 GENERAL REQUIREMENTS

The steps required for the determination of MWFRS wind loads on low-rise buildings are shown in Table 28.2-1.

Table 28.2-1. Steps to Determine Wind Loads on MWFRS Low-Rise Buildings.

Step 1: Determine risk category of building; see Table 1.5-1.
Step 2: Determine the basic wind speed, V, for applicable risk category; see Figure 26.5-1.
Step 3: Determine wind load parameters:

- Wind directionality factor, K_d; see Section 26.6 and Table 26.6-1.
- Exposure Category (B, C, or D); see Section 26.7.
- Topographic factor, K_{zt}; see Section 26.8 and Figure 26.8-1.
- Ground elevation factor, K_e; see Section 26.9 and Table 26.9-1.
- Enclosure classification; see Section 26.12.
- Internal pressure coefficient, (GC_{pi}); see Section 26.13 and Table 26.13-1.

Step 4: Determine velocity pressure exposure coefficient, K_z or K_h; see Table 26.10-1.
Step 5: Determine velocity pressure, q_z or q_h, from Equation (26.10-1).
Step 6: Determine external pressure coefficient, (GC_{pf}), for each load case using Section 28.3.2 for flat and gable roofs.

User Note: See Commentary Figure C28.3-2 for guidance on hip roofs.

Step 7: Calculate wind pressure, p, from Equation (28.3-1).

28.2.1 Wind Load Parameters Specified in Chapter 26 The following wind load parameters shall be determined in accordance with Chapter 26:

- Basic wind speed, V (Section 26.5);
- Wind directionality factor, K_d (Section 26.6);
- Exposure category (Section 26.7);
- Topographic factor, K_{zt} (Section 26.8);
- Ground elevation factor, K_e (Section 26.9);
- Velocity pressure exposure coefficient, K_z or K_h (Section 26.10);
- Enclosure classification (Section 26.12); and
- Internal pressure coefficient, (GC_{pi}) (Section 26.13).

@seismicisolation
@seismicisolation

28.3 WIND LOADS: MAIN WIND FORCE RESISTING SYSTEM

28.3.1 Design Wind Pressure for Low-Rise Buildings Design wind pressures for the MWFRS of low-rise buildings shall be determined by the following equation:

$$p = q_h K_d [(GC_{pf}) - (GC_{pi})] (\text{lb/ft}^2) \quad (28.3\text{-}1)$$

$$p = q_h K_d [(GC_{pf}) - (GC_{pi})] (\text{N/m}^2) \quad (28.3\text{-}1.\text{SI})$$

where

q_h = Velocity pressure evaluated at mean roof height h, as defined in Section 26.3;
K_d = Wind directionality factor, see Section 26.6;
(GC_{pf}) = External pressure coefficient from Section 28.3.2; and
(GC_{pi}) = Internal pressure coefficient from Table 26.13-1.

28.3.1.1 External Pressure Coefficients, (GC_{pf}) The combined gust-effect factor and external pressure coefficients used in this chapter, (GC_{pf}), are not permitted to be separated.

28.3.2 Load Cases Buildings shall be evaluated using each of the basic load cases and the torsional load cases acting independently in accordance with this section.

EXCEPTION: Design for the torsional cases is not required for

1. One-story buildings with h less than or equal to 30 ft (9.1 m),
2. One-story and two-story light-frame buildings, or
3. One-story and two-story buildings with flexible diaphragms.

28.3.2.1 Basic Load Cases The external pressure coefficient, (GC_{pf}), for basic load cases shall be determined in accordance with Figure 28.3-1. The building shall be evaluated with each corner taken as the windward corner, with loading patterns applied as shown, and with all zones being loaded simultaneously. Each corner shall be evaluated separately for the two load cases. In each load case, Zones 2E and 3E shall be located along the roof edge perpendicular to the ridge that is nearest the corner being evaluated. Combinations of external and internal pressures (see Table 26.13-1) shall be evaluated as required to obtain the most severe loadings.

For flat roofs, the roof angle, θ, shall be taken as 0, with the Zone 2/3 and Zone 2E/3E boundary located at the mid-width of the building.

The roof pressure coefficient, (GC_{pf}), when negative in Zones 2 and 2E, shall be applied in Zone 2/2E for a distance from the edge of roof equal to 0.5 times the horizontal dimension of the building parallel to the direction of the MWFRS being designed or 2.5 times the eave height at the windward wall, whichever is less; the remainder of Zone 2/2E extending to the ridge line shall use the pressure coefficient (GC_{pf}) for Zone 3/3E.

28.3.2.2 Torsional Load Cases The external pressure coefficient, (GC_{pf}), for torsional load cases shall be determined in accordance with Figure 28.3-2. For Zones 1 to 6 and 1E to 6E, Load Case 3 shall use Load Case 1 pressure coefficients from Figure 28.3-1, and Load Case 4 shall use Load Case 2 pressure coefficients from Figure 28.3-1. For zones designated with a "T" (1T to 6T), the pressure coefficients from Figure 28.3-2 shall be used.

The building shall be evaluated with each corner taken as the windward corner with loading patterns applied as shown and with all zones being loaded simultaneously. Each corner shall be evaluated separately for the two load cases. In each load case, Zones 2E and 3E shall be located along the roof edge perpendicular to the ridge that is nearest the corner being evaluated. Combinations of external and internal pressures (see Table 26.13-1) shall be evaluated as required to obtain the most severe loadings.

For flat roofs, the roof angle, θ, shall be taken as 0 with the Zone 2/3 and Zone 2E/3E boundary at the mid-width of the building. The roof pressure coefficient, (GC_{pf}), when negative in Zones 2 and 2E, shall be applied in Zone 2/2E for a distance from the edge of roof equal to 0.5 times the horizontal dimension of the building parallel to the direction of the MWFRS being designed or 2.5 times the eave height at the windward wall, whichever is less; the remainder of Zone 2/2E extending to the ridge line shall use the pressure coefficient, (GC_{pf}), for Zone 3/3E.

28.3.3 Total Horizontal Load The total horizontal shear shall not be less than that determined by neglecting the wind forces on the roof.

EXCEPTION: This provision does not apply to buildings using moment frames for the MWFRS.

28.3.4 Parapets The design wind pressure for the effect of parapets on MWFRS of low-rise buildings with flat, gable, or hip roofs shall be determined by the following equation:

$$p_p = q_p K_d (GC_{pn}) (\text{lb/ft}^2) \quad (28.3\text{-}2)$$

$$p_p = q_p K_d (GC_{pn}) (\text{N/m}^2) \quad (28.3\text{-}2.\text{SI})$$

where

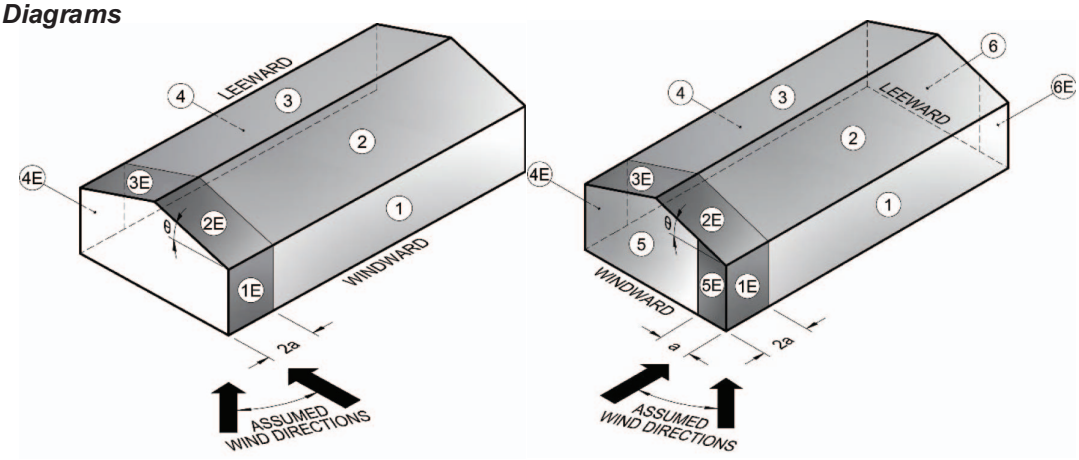
p_p = Combined net pressure on the parapet caused by the combination of the net pressures from the front and back parapet surfaces; plus (and minus) signs signify net pressure acting toward (and away from) the front (exterior) side of the parapet;
q_p = Velocity pressure evaluated at the top of the parapet;
K_d = Wind directionality factor, see Section 26.6; and
(GC_{pn}) = Combined net pressure coefficient: +1.5 for windward parapet, −1.0 for leeward parapet.

28.3.5 Roof Overhangs The positive external pressure on the bottom surface of windward roof overhangs shall be determined using $GC_p = 0.7$ in combination with the top surface pressures determined using Figure 28.3-1.

28.3.6 Minimum Design Wind Loads The wind pressure to be used in the design of the MWFRS for an enclosed or partially enclosed building shall not be less than 16 lb/ft^2 (0.77 kN/m^2) multiplied by the wall area of the building, and 8 lb/ft^2 (0.38 kN/m^2) multiplied by the roof area of the building projected onto a vertical plane normal to the assumed wind direction.

28.3.7 Horizontal Wind Loads on Open or Partially Enclosed Buildings with Transverse Frames and Pitched Roofs A horizontal pressure in the longitudinal direction (parallel to the ridge) that acts in combination with the roof load calculated in Section 27.4.3 for an open or partially enclosed building with transverse frames and a pitched roof ($\theta < 45$ degrees) shall be determined by the following equation:

$$p = q_h K_d [(GC_{pf})_{\text{windward}} - (GC_{pf})_{\text{leeward}}] K_B K_S \quad (28.3\text{-}3)$$



where

q_h = Velocity pressure evaluated at mean roof height h using the exposure as defined in Section 26.7.3;

@seismicisolation
@seismicisolation

Basic Load Cases

Diagrams

Load Case 1 **Load Case 2**

Notation

a = 10% of least horizontal dimension or 0.4 h,whichever is smaller, but not less than either 4% of least horizontal dimension or 3 ft (0.9 m).
EXCEPTION: For buildings with θ = 0 to 7° and a least horizontal dimension greater than 300 ft (90 m), dimension a shall be limited to a maximum of 0.8 h.

h = Mean roof height, ft (m), except that eave height shall be used for θ≤10°.

θ = Angle of plane of roof from horizontal, in degrees.

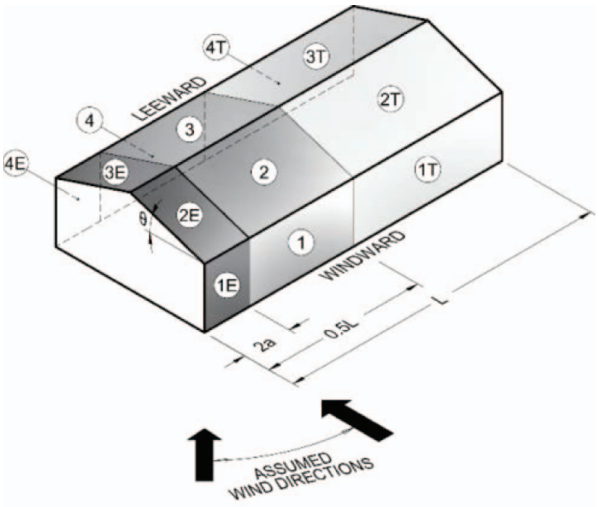
Load Case 1

Roof Angle θ (degrees)	Building Surface							
	1	2	3	4	1E	2E	3E	4E
0–5	0.40	–0.69	–0.37	–0.29	0.61	–1.07	–0.53	–0.43
20	0.53	–0.69	–0.48	–0.43	0.80	–1.07	–0.69	–0.64
30–45	0.56	0.21	–0.43	–0.37	0.69	0.27	–0.53	–0.48
90	0.56	0.56	–0.37	–0.37	0.69	0.69	–0.48	–0.48

Load Case 2

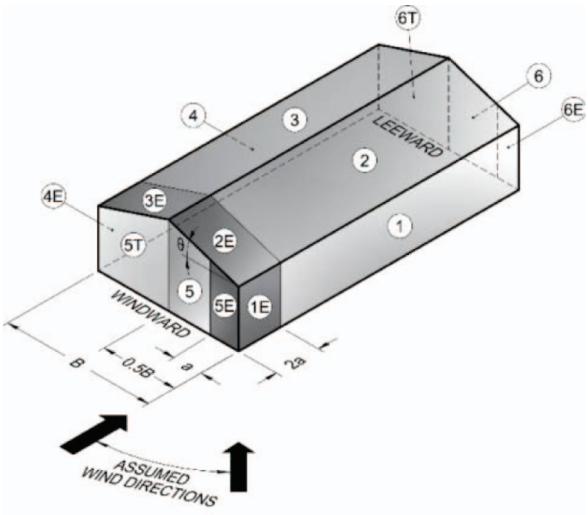
Roof Angle θ (degrees)	Building Surface											
	1	2	3	4	5	6	1E	2E	3E	4E	5E	6E
0–90	–0.45	–0.69	–0.37	–0.45	0.40	–0.29	–0.48	–1.07	–0.53	–0.48	0.61	–0.43

Notes



1. Plus and minus signs signify pressures acting toward and away from the surfaces, respectively.
2. For values of θ other than those shown, linear interpolation is permitted.

Figure 28.3-1. Basic load cases for main wind force resisting system [$h \leq 60$ ft ($h \leq 18.3$ m)]: external pressure coefficients, (GC_{pf}), for enclosed, partially enclosed, and partially open buildings—low-rise walls and roofs.



@seismicisolation

Torsional Load Cases

Diagrams

Load Case 3

Load Case 4

Notation

a = 10% of least horizontal dimension or 0.4 h, whichever is smaller, but not less than either 4% of least horizontal dimensionor 3ft (0.9 m).
EXCEPTION: For buildings with θ = 0 to 7° and a least horizontal dimension greater than 300 ft (90 m), dimension a shall be limited to a maximum of 0.8 h.

h = Mean roof height, in feet (meters), except that eave height shall be used for θ ≤ 10°.

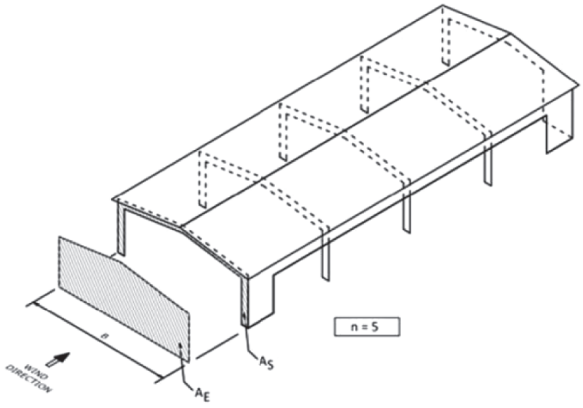
θ = Angle of plane of roof from horizontal, in degrees.

Load Case 3

	Building Surface			
Roof Angle θ (degrees)	**1T**	**2T**	**3T**	**4T**
0–5	0.10	–0.17	–0.09	–0.07
20	0.13	–0.17	–0.12	–0.11
30–45	0.14	0.05	–0.11	–0.09
90	0.14	0.14	–0.09	–0.09

Load Case 4

	Building Surface	
Roof Angle θ (degrees)	**5T**	**6T**
0–90	0.10	–0.07



Notes

1. Plus and minus signs signify pressures acting toward and away from the surfaces, respectively.
2. For values of θ other than those shown, linear interpolation is permitted.

Figure 28.3-2. Torsional load cases for main wind force resisting system [$h \leq 60$ ft ($h \leq 18.3$ m)]: external pressure coefficients, (GC_{pf}), for enclosed, partially enclosed, and partially open buildings—low-rise walls and roofs.

@seismicisolation

Diagram

Notation

B = Width of the building perpendicular to the ridge, ft (m)

A_S = Effective solid area of the end wall (i.e., the projected area of any portion of the end wall that would be exposed to the wind)

A_E = Total end wall area for an equivalent enclosed building

n = Number of frames, but shall not be taken as less than 3, even for 2-frame building.

Figure 28.3-3. Horizontal wind loads on open or partially enclosed buildings with transverse frames and pitched roofs: definitions of geometric terminology.

K_d = Wind directionality factor, see Section 26.6;

(GC_{pf}) = External pressure coefficient given in Figure 28.3-1 for Load Case 2, where building surfaces 5 and 5E shall be used to compute the average windward end wall pressure and building surfaces 6 and 6E shall be used to compute the average leeward end wall pressure;

K_B = Frame width factor = $1.8–0.01\,B$, $B < 100$ ft ($B < 30.5$ m), or 0.8, $B \geq 100$ ft ($B \geq 30.5$ m);

K_S = Shielding factor = $0.60 + 0.073(n - 3) + (1.25\,\phi^{1.8})$;

ϕ = Solidity ratio = A_S/A_E;

B = Width of the building perpendicular to the ridge, ft (m);

n = Number of frames, but shall not be taken as less than 3, even for small 2-frame building;

A_S = Effective solid area of the end wall, that is, the projected area of any portion of the end wall that would be exposed to the wind (Figure 28.3-3); and

A_E = Total end wall area for an equivalent enclosed building (Figure 28.3-3).

The total longitudinal force F to be resisted by the MWFRS shall be determined by Equation (28.3-4):

$$F = pA_E \tag{28.3-4}$$

Equation (28.3-3) is applicable to buildings with open end walls and with end walls fully or partially enclosed with cladding. For all cases, A_E shall be the area that is equivalent to the end wall fully enclosed. The longitudinal force, F, given by Equation (28.3-4) represents the total force for which the MWFRS longitudinal bracing shall be designed. The distribution to each sidewall shall be based on the force F applied at the centroid of the end wall area A_E.

Fascia load need not be considered separately if fascia areas are included in the A_S calculation.

28.4 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

No consensus standards and other documents that shall be considered part of this standard are referenced in this chapter.

CHAPTER 29
WIND LOADS ON BUILDING APPURTENANCES AND OTHER STRUCTURES: MAIN WIND FORCE RESISTING SYSTEM (DIRECTIONAL PROCEDURE)

29.1 SCOPE

29.1.1 Structure Types This chapter applies to the determination of wind loads on building appurtenances (such as rooftop structures and rooftop equipment) and other structures of all heights (such as solid freestanding walls and freestanding solid signs, chimneys, tanks, circular bins, silos, open signs, single-plane open frames, ground-mounted fixed-tilt solar panel systems, and trussed towers) using the Directional Procedure.

The steps required for the determination of wind loads on building appurtenances and other structures are shown in Table 29.1-1. The steps required to determine wind loads on the Main Wind Force Resisting System (MWFRS) on circular bins, silos, and tanks are shown in Table 29.1-2.

User Note: Use Chapter 29 to determine wind pressures on the MWFRS of solid freestanding walls, freestanding solid signs, chimneys, tanks, open signs, single-plane open frames, ground-mounted fixed-tilt solar panel systems, and trussed towers. Wind loads on rooftop structures and equipment may be determined from the provisions of this chapter. The wind pressures are calculated using specific equations, based upon the Directional Procedure.

29.1.2 Conditions An appurtenance or structure that has design wind loads, determined in accordance with this section, shall comply with all of the following conditions:

1. Structure is a regular-shaped structure as defined in Section 26.2; and
2. Structure does not have response characteristics making it subject to across-wind loading, vortex shedding, or instability caused by galloping or flutter; nor does it have a site location for which channeling effects or buffeting in the wake of upwind obstructions warrant special consideration.

29.1.3 Limitations The provisions of this chapter take into consideration the load magnification effect caused by gusts in resonance with along-wind vibrations of flexible structures. Structures that do not meet the requirements of Section 29.1.2, or that have unusual shapes or response characteristics, shall be designed using recognized literature documenting such wind load effects or shall use the Wind Tunnel Procedure specified in Chapter 31.

29.1.4 Shielding There shall be no reductions in velocity pressure caused by apparent shielding afforded by buildings and other structures or terrain features.

Table 29.1-1. Steps to Determine Wind Loads on MWFRS Rooftop Equipment and Other Structures.

Step 1: Determine the Risk Category of building or other structure; see Table 1.5-1.

Step 2: Determine the basic wind speed, V, for applicable Risk Category; see Figure 26.5-1.

Step 3: Determine wind load parameters:
- Wind directionality factor, K_d; see Section 26.6 and Table 26.6-1.
- Exposure Category B, C, or D; see Section 26.7.
- Topographic factor, K_{zt}; see Section 26.8 and Figure 26.8-1.
- Ground elevation factor, K_e; see Section 26.9 and Table 26.9-1.
- Gust-effect factor, G; see Section 26.11, except for rooftop equipment and ground-mounted fixed-tilt solar panel systems.
- Combined (GC_r) factor for rooftop equipment; see Section 29.4.1.
- Combined (GC_{pn} and GC_{pm}) factors for ground-mounted fixed-tilt solar panel systems; see Section 29.4.5.

Step 4: Determine velocity pressure exposure coefficient, K_z or K_h; see Table 26.10-1.

Step 5: Determine velocity pressure q_z or q_h; see Equation (26.10-1).

Step 6: Determine force coefficient, C_f, except for rooftop equipment and ground-mounted fixed-tilt solar panel systems:
- Solid freestanding signs or solid freestanding walls, Figure 29.3-1.
- Chimneys, tanks, Figure 29.4-1.
- Open signs, single-plane open frames, Figure 29.4-2.
- Trussed towers, Figure 29.4-3.
- Rooftop equipment, using combined (GC_r) factors listed in Section 29.4.1.
- Rooftop solar panels, Figure 29.4-7 and Equation (29.4-6), or Figure 29.4-8.
- Ground-mounted fixed-tilt solar panel systems, using combined (GC_{pn} and GC_{pm}) factors, see Section 29.4.5.2.

Step 7: Calculate wind force, F, or pressure, p, and moment, M:
- Equation (29.3-1) for signs and walls.
- Equations (29.4-2) and (29.4-3) for rooftop structures and equipment.
- Equation (29.4-1) for other structures.
- Equation (29.4-5) or (29.4-7) for rooftop solar panels.
- Equations (29.4-8) and (29.4-9) for ground-mounted fixed-tilt solar panel systems.

@seismicisolation

Table 29.1-2. Steps to Determine Wind Loads on MWFRS Circular Bins, Silos, and Tanks.

Step 1: Determine the Risk Category of structure; see Table 1.5-1.
Step 2: Determine the basic wind speed, V, for applicable Risk Category; see Figure 26.5-1.
Step 3: Determine wind load parameters:
- Wind directionality factor, K_d; see Section 26.6 and Table 26.6-1.
- Exposure Category B, C, or D; see Section 26.7.
- Topographic factor, K_{zt}; see Section 26.8 and Figure 26.8-1.
- Ground elevation factor, K_e; see Section 26.9 and Table 26.9-1.
- Enclosure classification, see Section 26.12.
- Internal pressure coefficient, (GC_{pi}), see Table 26.13-1.
- Gust-effect factor, G; see Section 26.11.

Step 4: Determine velocity pressure exposure coefficient, K_z or K_h; see Table 26.10-1.
Step 5: Determine velocity pressure q_h; see Equation (26.10-1).
Step 6: Determine force coefficient for walls, see Sections 29.4.2.1 and 29.4.2.4.
Step 7: Determine external pressure coefficient (GC_p) for roofs and undersides if elevated, see Sections 29.4.2.2 and 29.4.2.3.
Step 8: Calculate wind force, F, or pressure, p:
- Equation (29.4-1) for walls.
- Equation (29.4-4) for roofs.

29.2 GENERAL REQUIREMENTS

29.2.1 Wind Load Parameters Specified in Chapter 26 The following wind load parameters shall be determined in accordance with Chapter 26:

- Basic wind speed, V (Section 26.5);
- Wind directionality factor, K_d (Section 26.6);
- Exposure category (Section 26.7);
- Topographic factor, K_{zt} (Section 26.8);
- Ground elevation factor, K_e (Section 26.9); and
- Enclosure classification (Section 26.12).

29.3 DESIGN WIND LOADS: SOLID FREESTANDING WALLS AND SOLID SIGNS

29.3.1 Solid Freestanding Walls and Solid Freestanding Signs The design wind force for solid freestanding walls and solid freestanding signs shall be determined by the following formula:

$$F = q_h K_d G C_f A_s \text{ (lb)} \qquad (29.3\text{-}1)$$

$$F = q_h K_d G C_f A_s \text{ (N)} \qquad (29.3\text{-}1.\text{SI})$$

where

q_h = Velocity pressure evaluated at height h (defined in Figure 29.3-1) as determined in accordance with Section 26.10;
K_d = Wind directionality factor, see Section 26.6;
G = Gust-effect factor from Section 26.11;
C_f = Net force coefficient from Figure 29.3-1; and
A_s = Gross area of the solid freestanding wall or freestanding solid sign, ft^2 (m^2).

29.3.2 Solid Attached Signs The design wind pressure on a solid sign attached to the wall of a building, where the plane of the sign is parallel to and in contact with the plane of the wall, and the sign does not extend beyond the side or top edges of the wall, shall be determined using procedures for wind pressures on walls in accordance with Chapter 30 and setting the internal pressure coefficient, (GC_{pi}), equal to 0.

This procedure shall also be applicable to solid signs attached to but not in direct contact with the wall, provided that the gap between the sign and wall is no more than 3 ft (0.9 m) and the edge of the sign is at least 3 ft (0.9 m) in from free edges of the wall (i.e., side and top edges and bottom edges of elevated walls).

29.4 DESIGN WIND LOADS: OTHER STRUCTURES

The design wind force for other structures (chimneys, tanks, open signs, single-plane open frames, and trussed towers), whether ground or roof mounted, shall be determined by the following equation:

$$F = q_z K_d G C_f A_f \text{ (lb)} \qquad (29.4\text{-}1)$$

$$F = q_z K_d G C_f A_f \text{ (N)} \qquad (29.4\text{-}1.\text{SI})$$

where

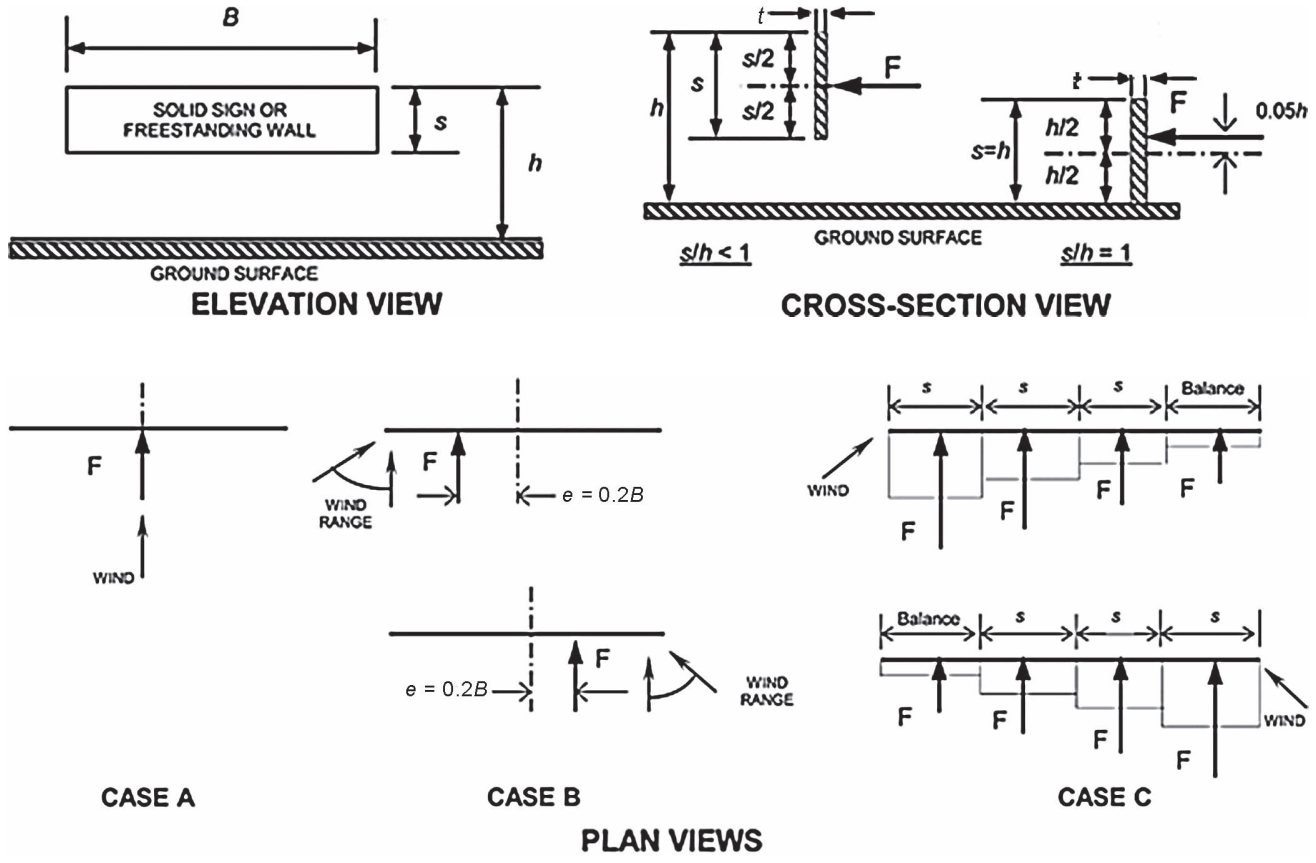
q_z = Velocity pressure evaluated at height z, as defined in Section 26.10, of the centroid of area A_f;
K_d = Wind directionality factor, see Section 26.6;
G = Gust-effect factor from Section 26.11;
C_f = Force coefficients from Figures 29.4-1 through 29.4-4; and
A_f = Projected area normal to the wind except where C_f is specified for the actual surface area, ft^2 (m^2).

Determination of G, C_f, and A_f for structures found in petrochemical and other industrial facilities that are not otherwise addressed in ASCE 7 is permitted in accordance with *Wind Loads for Petrochemical and Other Industrial Facilities* (ASCE 2011). Determination of G, C_f, and A_f for lighting system support poles is permitted in accordance with ASCE 72.

29.4.1 Rooftop Structures and Equipment for Buildings The lateral force, F_h, and vertical force, F_v, for rooftop structures and equipment, except as otherwise specified for roof-mounted solar panels (Sections 29.4.3 and 29.4.4) and structures identified in Section 29.4, shall be determined as specified.

The resultant lateral force, F_h, shall be determined from Equation (29.4-2) and applied at a height above the roof surface equal to or greater than the centroid of the projected area, A_f

$$F_h = q_h K_d (GC_r) A_f \text{ (lb)} \qquad (29.4\text{-}2)$$



$$F_h = q_h K_d (GC_r) A_f \text{ (N)} \qquad (29.4\text{-}2.\text{SI})$$

where

(GC_r) = 1.9 for rooftop structures and equipment with A_f less than $0.1Bh$; (GC_r) shall be permitted to be reduced linearly from 1.9 to 1.0 as the value of A_f is increased from $0.1Bh$ to Bh;
q_h = Velocity pressure evaluated at mean roof height of the building;
K_d = Wind directionality factor, see Section 26.6; and
A_f = Vertical projected area of the rooftop structure or equipment on a plane normal to the direction of wind, ft^2 (m^2).

@seismicisolation

Diagrams

Notation

B = Horizontal dimension of wall or sign, ft (m)
e = Eccentricity of force, ft (m)
F = Design wind force for other structures, lb (N)
h = Height of the wall or sign, ft (m)
L_r = Horizontal dimension of return corner, ft (m)
$R_{min} = t/\min$ (B and s)
$R_{max} = t/\max$ (B and s)
s = Vertical dimension of the wall or sign, ft (m)
t = Thickness of the wall or sign, ft (m)
ε = Ratio of solid area to gross area

Force Coefficients, C_f, for Case A and Case B

Clearance Ratio, s/h	Aspect Ratio, B/s

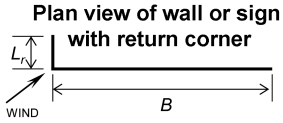
Figure 29.3-1. Design wind loads (all heights): force coefficients, C_f, for other structures—solid freestanding walls and solid freestanding signs.



@seismicisolation

Force Coefficients, C_f, for Case C

Region (horizontal distance from windward edge)	Aspect Ratio, B/s										
	2	3	4	5	6	7	8	9	10	13	≥45
0 to s	2.25	2.60	2.90	3.10*	3.30*	3.40*	3.55*	3.65*	3.75*	4.00*	4.30*
s to $2s$	1.50	1.70	1.90	2.00	2.15	2.25	2.30	2.35	2.45	2.60	2.55
$2s$ to $3s$		1.15	1.30	1.45	1.55	1.65	1.70	1.75	1.85	2.00	1.95
$3s$ to $10s$			1.10	1.05	1.05	1.05	1.05	1.00	0.95		
$3s$ to $4s$										1.50	1.85
$4s$ to $5s$										1.35	1.85
$5s$ to $10s$										0.90	1.10
$> 10s$										0.55	0.55

*Values shall be multiplied by the following reduction factor when a return corner is present:

L_r/S	*Reduction Factor*
0.3	0.90
1.0	0.75
≥2	0.60

Notes

1. Force coefficients for solid walls or signs with openings less than 30% of gross area shall be permitted to be multiplied by the reduction factor $(1 - (1 - \varepsilon)^{1.5})$.
2. To allow for both normal and oblique wind directions, the following cases shall be considered:
   For $s/h < 1$:
   Case A: Resultant force acts normal to the face of the wall or sign through the geometric center.
   Case B: Resultant force acts normal to the face of the wall or sign at a distance from the geometric center toward the windward edge equal to 0.2 times the average width of the wall or sign.
   For double-faced signs with all sides enclosed and $R_{max} \le 0.4$, it is permitted to use force eccentricity, $e = (0.2 - 0.25R_{max})B$. For double-faced signs with all sides enclosed and $R_{min} \le 0.75$, it is permitted to multiply tabulated C_f values in Cases A and B by the reduction factor, $(1 - 0.133R_{min})$.
   For $B/s \ge 2$, Case B need not be considered, while Case C must be considered;
   Case C: Resultant forces act normal to the face of the wall or sign through the geometric centers of each region.
   For $s/h = 1$:
   The same cases as above except that the vertical locations of the resultant forces occur at a distance above the geometric center equal to 0.05 times the average height of the wall or sign.
3. For Case C where $s/h > 0.8$, for efficients shall be multiplied by the reduction factor $(1.8 - s/h)$. It is permitted to apply this reduction with those specified in Note 2.
4. Linear interpolation is permitted for values of s/h, B/s, and L_r/s other than shown.

Figure 29.3-1 (*Continued*). Design wind loads (all heights): force coefficients, C_f, for other structures—solid freestanding walls and solid freestanding signs.

@seismicisolation

Force Coefficients, C_f

Cross Section	Type of Surface	h/D = 1	h/D = 7	h/D = 25
Square (wind normal to face)	All	1.3	1.4	2.0
Square (wind along diagonal)	All	1.0	1.1	1.5
Hexagonal or octagonal	All	1.0	1.2	1.4
Round, $D\sqrt{q_z} > 2.5$	Moderately smooth ($D'/D < 0.02$)	0.5	0.6	0.7
$D\sqrt{q_z} > 5.3$ (in SI)	Rough ($0.02 \le D'/D < 0.08$)	0.7	0.8	0.9
	Very rough ($D'/D = 0.08$)	0.8	1.0	1.2
Round, $D\sqrt{q_z} \le 2.5$	All	0.7	0.8	1.2
$D\sqrt{q_z} \le 5.3$ (in SI)				

Notation

D = Diameter of circular cross section and least horizontal dimension of square, hexagonal, or octagonal cross sections at elevation under consideration, ft (m).
D' = Depth of protruding elements such as ribs and spoilers, ft (m).
h = Height of structure, ft (m).
q_z = Velocity pressure evaluated at height z above ground, lb/ft^2 (N/m^2).

Notes

1. Design wind force shall be calculated based on the area of the structure projected on a vertical plane normal to the wind direction. The force shall be assumed to act parallel to the wind direction.
2. Linear interpolation is permitted for h/D values other than shown.

Figure 29.4-1. Other structures (all heights): force coefficients, C_f, for chimneys, tanks, and similar structures.

Force Coefficients, C_f

ε	Flat-Sided Members	Rounded Members: $D\sqrt{q_z} \le 2.5$ ($D\sqrt{q_z} \le 5.3$) s.i	Rounded Members: $D\sqrt{q_z} > 2.5$ ($D\sqrt{q_z} > 5.3$) s.i
<0.1	2.0	1.2	0.8
0.1 to 0.29	1.8	1.3	0.9
0.3 to 0.7	1.6	1.5	1.1

Notation

ε = Ratio of solid area to gross area.
D = Diameter of a typical round member, ft (m).
q_z = Velocity pressure evaluated at height z above ground, lb/ft^2 (N/m^2).

Notes

1. Signs with openings making up 30% or more of the gross area are classified as open signs.
2. Calculation of the design wind forces shall be based on the area of all exposed members and elements projected on a plane normal to the wind direction. Forces shall be assumed to act parallel to the wind direction.
3. Area, A_f, consistent with these force coefficients is the solid area projected normal to the wind direction.

Figure 29.4-2. Other structures (all heights): force coefficients, C_f, for open signs and single-plane open frames.

@seismicisolation

Force Coefficients, C_f

Tower Cross Section	C_f
Square	$4.0\varepsilon^2 - 5.9\varepsilon + 4.0$
Triangle	$3.4\varepsilon^2 - 4.7\varepsilon + 3.4$

Notation

ε = Ratio of solid area to gross area of one tower face for the segment under consideration.

Notes

1. For all wind directions considered, the area, A_f, consistent with the specified force coefficients shall be the solid area of a tower face projected on the plane of that face for the tower segment under consideration.
2. Specified force coefficients are for towers with structural angles or similar flat-sided members.
3. For towers containing rounded members, it is acceptable to multiply the specified force coefficients by the following factor when determining wind forces on such members:

$$0.51\varepsilon^2 + 0.57, \text{ but not} > 1.0$$

4. Wind forces shall be applied in the directions resulting in maximum member forces and reactions. For towers with square cross sections, wind forces shall be multiplied by the following factor when the wind is directed diagonally along a tower

$$1 + 0.75\varepsilon, \text{ but not} > 1.2$$

5. Wind forces on tower appurtenances, such as ladders, conduits, lights, and elevators, shall be calculated using appropriate force coefficients for these elements.
6. Loads caused by ice accretion, as described in Chapter 10, shall be accounted for.

Figure 29.4-3. Other structures (all heights): force coefficients, C_f, for open structures—trussed towers.

The vertical uplift force, F_v, on rooftop structures and equipment shall be determined from Equation (29.4-3)

$$F_v = q_h K_d (GC_r) A_r \text{ (lb)} \quad (29.4\text{-}3)$$

$$F_v = q_h K_d (GC_r) A_r \text{ (N)} \quad (29.4\text{-}3.\text{SI})$$

where

(GC_r) = 1.5 for rooftop structures and equipment with A_r less than $0.1BL$; (GC_r) shall be permitted to be reduced linearly from 1.5 to 1.0 as the value of A_r is increased from $0.1BL$ to BL;
q_h = Velocity pressure evaluated at the mean roof height of the building;
K_d = Wind directionality factor, see Section 26.6; and
A_r = Horizontal projected area of rooftop structure or equipment, ft^2 (m^2).

29.4.2 Design Wind Loads: Circular Bins, Silos, and Tanks with $h \le 120$ ft ($h \le 36.5$ m), $D \le 120$ ft ($D \le 36.5$ m), and $0.25 \le HD \le 4$ Grouped circular bins, silos, and tanks of similar size with center-to-center spacing greater than two diameters shall be treated as isolated structures. For spacings less than 1.25 diameters, the structures shall be treated as grouped, and the wind pressure shall be determined from Section 29.4.2.4. For intermediate spacings, linear interpolation of the C_p (or C_f) values shall be used.

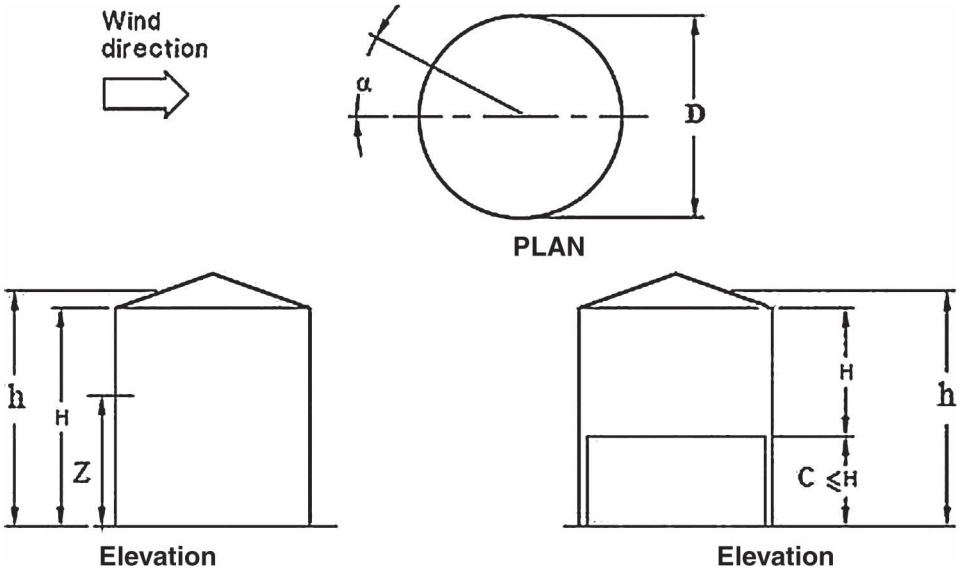
29.4.2.1 External Walls of Isolated Circular Bins, Silos, and Tanks To determine the overall drag on circular bins, silos, and tanks using Equation (29.4-1), a force coefficient C_f of 0.63, based on the projected wall area Dh_c, is permitted to be used in lieu of Figure 29.4-1, provided that all of the following conditions are met:

(a) h_c/D is in the range of 0.25 to 4.0 and the cylinder (diameter D) is standing on the ground or supported by columns; and
(b) Clearance height, C, is less than or equal to the height of the solid, cylinder h_c, as shown in Figure 29.4-4; and
(c) Tank surface is moderately smooth, as defined in Figure 29.4-1.

29.4.2.2 Roofs of Isolated Circular Bins, Silos, and Tanks The net design pressures on the roofs of circular bins, silos, and tanks shall be determined from Equation (29.4-4)

$$p = q_h K_d (GC_p - (GC_{pi})) \text{ (lb/ft}^2\text{)} \quad (29.4\text{-}4)$$

$$p = q_h K_d (GC_p - (GC_{pi})) \text{(N/m}^2\text{)} \quad (29.4\text{-}4.\text{SI})$$



where

q_h = Velocity pressure for all surfaces evaluated at mean roof height h;
K_d = Wind directionality factor, see Section 26.6;
C_p = External pressure coefficient from Figure 29.4-5 for roofs;
(GC_{pi}) = Internal pressure coefficient for roofed structures from Section 26.13; and
G = Gust-effect factor from Section 26.11.

The external pressures on the conical, flat, or dome roofs (roof angle less than 10 degrees) of circular bins, silos, or tanks shall be

@seismicisolation

Diagrams

Notation

C = Clearance height above the ground, ft (m).
D = Diameter of a circular structure, ft (m).
h = Mean roof height, ft (m).
H = Solid cylinder height, ft (m).
Z = Height to centroid of projected area of circular structure, ft (m).
α = Angle from wind direction to a point on the wall of a circular bin, silo, or tank (degrees).

Figure 29.4-4. Other structures, design wind loads for main wind force resisting systems [$h < 120$ ft ($h < 36.6$ m)]: circular bins, silos, and tanks on the ground or supported by columns, where $D \leq 120$ ft ($D \leq 36.6$ m), $0.25 \leq H/D < 4.0$.

equal to the external pressure coefficients, C_p, given in Figure 29.4-5 for Zones 1 and 2. The external pressures for dome roofs (roof angle greater than 10 degrees) shall be determined from Figure 27.3-2.

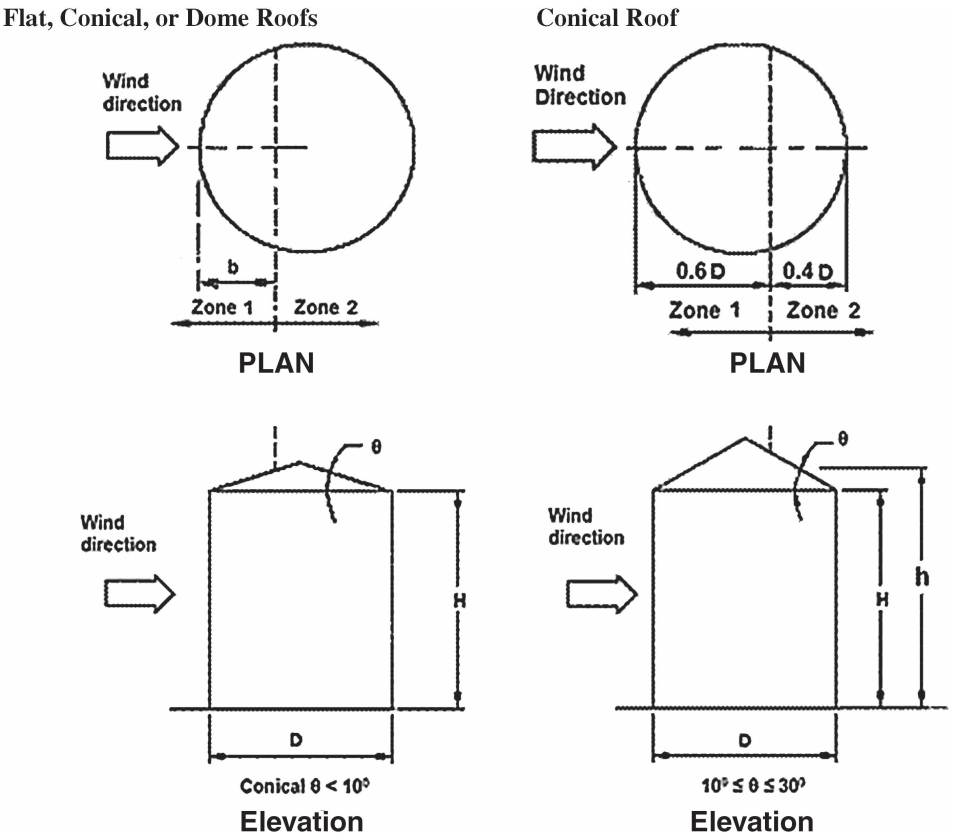
29.4.2.3 Undersides of Isolated Elevated Circular Bins, Silos, and Tanks External pressure coefficients, C_p, for the underside of elevated circular bins, silos, or tanks with clearance height, C, above ground less than or equal to the solid cylinder height, H, shall be taken as 0.8 and −0.6. For structures with clearance height above ground of less than or equal to one-third of the cylinder height, use linear interpolation between these values and $C_p = 0.0$, according to the ratio of C/h, where C and h are defined, as shown in Figure 29.4-4.

29.4.2.4 Roofs and Walls of Grouped Circular Bins, Silos, and Tanks For closely spaced groups of three or more circular bins, silos, or tanks with center-to-center spacing less than $1.25D$, roof pressure coefficients, C_p, and drag force coefficient, C_f, on projected walls shall be calculated using Figure 29.4-6. The net design pressures on the roofs shall be determined from Equation (29.4-4). The overall drag shall be calculated based on Equation (29.4-1).

29.4.3 Rooftop Solar Panels for Buildings of All Heights with Flat Roofs or Gable or Hip Roofs with Slopes Less Than 7 Degrees As illustrated in Figure 29.4-7, the design wind pressure for rooftop solar panels apply to those located on enclosed or partially enclosed buildings of all heights with flat roofs, or with gable or hip roof slopes with $\theta \leq 7°$, with panels conforming to

$L_p \leq 6.7$ ft (2.04 m),
$\omega \leq 35°$,
$h_1 \leq 2$ ft (0.61 m),
$h_2 \leq 4$ ft (1.22 m),

and with a minimum gap of 0.25 in. (6.4 mm) provided between all panels, and the spacing of gaps between panels not exceeding 6.7 ft (2.04 m). In addition, the minimum horizontal clear distance between the panels and the edge of the roof shall be the larger of $2(h_2 - h_{pt})$ and 4 ft (1.2 m) for the design pressures in this section to apply. The design wind pressure for rooftop solar panels shall be determined by Equations (29.4-5) and (29.4-6):



$$p = q_h K_d (GC_{rn}) \text{ (lb/ft}^2\text{)} \quad (29.4\text{-}5)$$

$$p = q_h K_d (GC_{rn}) \text{ (N/m}^2\text{)} \quad (29.4\text{-}5.\text{SI})$$

where q_h is the velocity pressure for all surfaces evaluated at mean roof height, h, and K_d is the wind directionality factor; see Section 26.6.

@seismicisolation

Diagrams

Notation

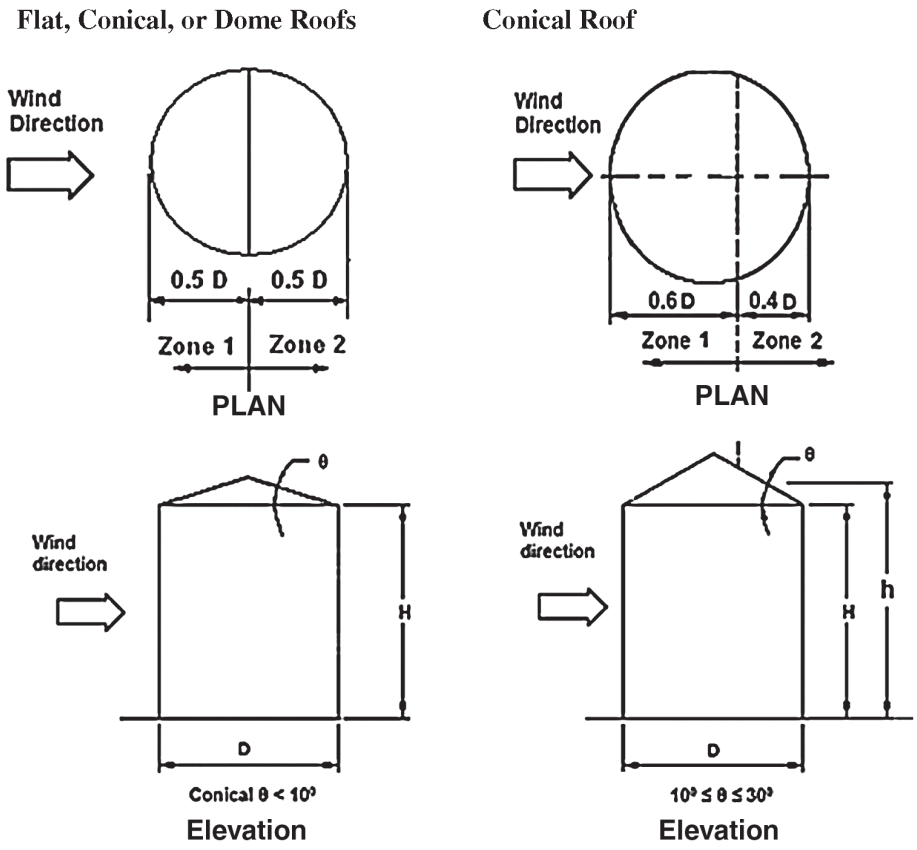
b = Determined below, ft (m), dependent on H/D for roofs with average θ less than 10 degrees.
h = Mean roof height, ft (m).
H = The solid cylinder height, ft (m).
D = Diameter of a circular structure, ft (m).
θ = Angle of plane of roof from horizontal, in degrees.

External Pressure Coefficients, C_p

Zone 1	−0.8
Zone 2	−0.5

Notes

For roofs with average θ less than 10 degrees, the dimension, b, shall be determined as follows:



H/D	b
0.25	0.2D
0.5	0.5D
≥1.0	0.1h + 0.6D

Linear interpolation shall be permitted.

Figure 29.4-5. Other structures, design wind loads for main wind force resisting systems [h<120 ft (h<36.6 m)]: external pressure coefficients, C_p, for isolated roofs of circular bins, silos, and tanks, where $D \leq 120$ ft ($D \leq 36.6$ m), $0.25 \leq H/D < 4.0$.

@seismicisolation

Notation

A = Effective wind area, ft^2 (m^2).
A_n = Normalized wind area, non dimensional.
d_1 = For rooftop solar array, horizontal distance orthogonal to the panel edge to an adjacent panel or the building edge, ignoring any rooftop equipment in Figure 29.4-7, ft (m).
d_2 = For rooftop solar arrays, horizontal distance from the edge of one panel to the nearest edge in the next row in Figure 29.4-7, ft (m).
h = Mean roof height of a building except that eave height shall be used for roof angle θ less than or equal to 10°, ft (m).
h_1 = Height of the gap between the panels and the roof surface, ft (m).
h_2 = Height of a solar panel above the roof at the upper edge of the panel, ft (m).
h_{pt} = Mean parapet height above the adjacent roof surface for use with Equation (29.4-5), ft (m).
L_p = Panel chord length.
W_L = Width of a building on its longest side in Figure 29.4-7, ft (m).
W_S = Width of a building on its shortest side in Figure 29.4-7, ft (m).
γ_E = Array edge factor as defined in Section 29.4.4.
θ = Angle of plane of roof from horizontal, in degrees.
ω = Angle that the solar panel makes with the roof surface in Figure 29.4-7, degrees.

Notes

1. (GC_{rn}) acts toward (+) and away (–) from the top surface of the panels.
2. Linear interpolation is allowed for ω between 5 and 15 degrees.
3. $A_n = (1,000/[\max(L_b, 15)^2]A$, where A is the effective wind area of the structural element of the solar panel being considered, and L_b is the minimum of $0.4(h\mathrm{W_L})^{0.5}$ or h or W_s, ft (m).

Figure 29.4-7 (*Continued*). Design wind loads (all heights): rooftop solar panels for enclosed and partially enclosed buildings, roof $\theta \le 7°$.

$$(GC_{rn}) = (\gamma_p)(\gamma_c)(\gamma_E)(GC_{rn})_{\text{nom}} \tag{29.4-6}$$

where

γ_p = $\min(1.2, 0.9 + h_{pt}/h)$;
γ_c = $\max(0.6 + 0.06L_p, 0.8)$; and
γ_E = 1.5 for uplift loads on panels that are exposed and within a distance $1.5(L_p)$ from the end of a row at an exposed edge of the array; $\gamma_E = 1.0$ elsewhere for uplift loads and for all downward loads, as illustrated in Figure 29.4-7; a panel is defined as exposed if d_1 to the roof edge $> 0.5h$ and one of the following applies:

1. d_1 to the adjacent array $> \max(4h_2$, 4 ft (1.2 m), or
2. d_2 to the next adjacent panel $> \max(4h_2$, 4 ft (1.2 m).

$(GC_{rn})_{nom}$ is the nominal net pressure coefficient for rooftop solar panels as determined from Figure 29.4-7.

When $\omega \le 2°$, $h_2 \le 0.83$ ft (0.25 m), a minimum gap of 0.25 in. (6.4 mm) is provided between all panels, and the spacing of gaps between panels does not exceed 6.7 ft (2.04 m), the procedure of Section 29.4.4 shall be permitted.

The roof shall be designed for both of the following:

1. The case where solar collectors are present. Wind loads acting on solar collectors in accordance with this section shall be applied simultaneously with roof wind loads specified in other sections acting on areas of the roof not covered by the plan projection of solar collectors. For this case, roof wind loads specified in other sections need not be applied on areas of the roof covered by the plan projection of solar collectors.
2. Cases where the solar arrays have been removed.

29.4.4 Rooftop Solar Panels Parallel to the Roof Surface on Buildings of All Heights and Roof Slopes The design wind pressures for rooftop solar panels located on enclosed or partially enclosed buildings of all heights, with panels parallel to the roof surface, with a tolerance of 2 degrees and with a maximum height above the roof surface, h_2, not exceeding 10 in. (0.25 m), shall be determined in accordance with this section. A minimum gap of 0.25 in. (6.4 mm) shall be provided between all panels, with the spacing of gaps between panels not exceeding 6.7 ft (2.04 m). In addition, the array shall be located at least $2h_2$ from the roof edge, a gable ridge, or a hip ridge. The design wind pressure for rooftop solar collectors shall be determined by Equation (29.4-7)

$$p = q_h K_d (GC_p)(\gamma_E)(\gamma_a)\ (\mathrm{lb/ft^2}) \tag{29.4-7}$$

$$p = q_h K_d (GC_p)(\gamma_E)(\gamma_a)\ (\mathrm{N/m^2}) \tag{29.4-7.SI}$$

where

q_h = Velocity pressure for all surfaces evaluated at mean roof height, h;
K_d = Wind directionality factor, see Section 26.6;
(GC_p) = External pressure coefficient for C&C of roofs with respective roof zoning, determined from Figures 30.3-2A-I through 30.3-7 or 30.5-1;
γ_E = Array edge factor = 1.5 for uplift loads on panels that are exposed and within a distance of $2h_2$ from an edge of the array; $\gamma_E = 1.0$ elsewhere for uplift loads and for all downward loads, as illustrated in Figure 29.4-7; a panel is defined as exposed if d_1 to the roof edge $> 0.5h$ and one of the following applies:
d_1 to the adjacent array $> 2h_2$ or
d_2 to the next adjacent panel $> 2h_2$; and
γ_a = Solar panel pressure equalization factor, defined in Figure 29.4-8.

@seismicisolation

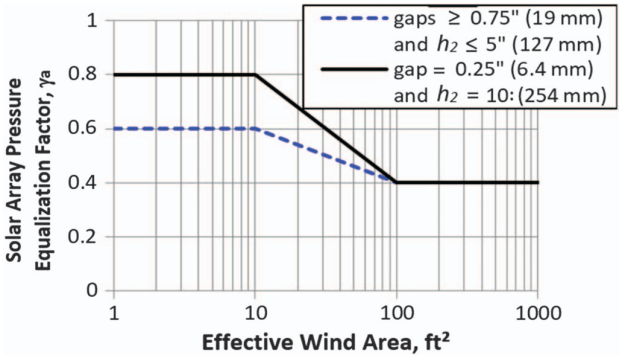

Figure 29.4-8. Solar panel pressure equalization factor, γ_a, for enclosed and partially enclosed buildings of all heights.
Note: Bilinear interpolation between the solid line and the dashed line is permitted. Change to = signs for solid line.

The roof shall be designed for both of the following:

1. In the case where solar panels are present, wind loads acting on solar collectors in accordance with this section shall be applied simultaneously with roof wind loads specified in other sections acting on areas of the roof not covered by the plan projection of solar collectors. For this case, roof wind loads specified in other sections need not be applied on areas of the roof covered by the plan projection of solar collectors.
2. Case where the solar panels have been removed.

29.4.5 Ground-Mounted Fixed-Tilt Solar Panel Systems

29.4.5.1 Scope Wind loads shall be calculated in accordance with Sections 29.4.5.2 and 29.4.5.3 for ground-mounted fixed-tilt solar photovoltaic (PV) panel systems installed in rows satisfying the following geometric limitations:

6 ft (1.8 m) ≤ L_c ≤ 14 ft (4.4 m)
$(W_g/L_c) \geq 7$
$0° \leq \omega \leq 60°$
$0.5 \leq (h/L_c) \leq 0.8$
$0.20 \leq (L_c/S) \leq 0.60$
$s_p \leq 0.014L_c$
$S_L \leq 0.25L_c$
$S_T \leq 2S$

Number of rows ≥3
The rows have the same chord length.
The ratio of area blocked by support framing to total area below lowest edge of panels ≤8% over any length of $4L_c$,

where

L_c = Panel chord length, ft (m).
W_g = Shortest row length in array, ft (m).
ω = Angle between the solar panels and the ground surface, degrees.
h = Mean height of panel, ft (m).
S = Center-to-center row spacing, ft (m).
s_p = Gap between adjacent panels in both directions.
S_L = Horizontal distance in longitudinal direction of open area within a single row.
S_T = Horizontal distance in transverse direction of open area between adjacent rows.

29.4.5.2 Design Wind Loads The design force, F_n, and design moment about the center-of-plane of panels, M_c, for ground-mounted solar panels shall be determined by Equation (29.4-8) and Equation (29.4-9), respectively:

$$F_n = q_h K_d [\pm(GC_{gn})] A \text{ (lb)} \quad (29.4\text{-}8)$$

$$F_n = q_h K_d [\pm(GC_{gn})] A \text{ (N)} \quad (29.4\text{-}8.SI)$$

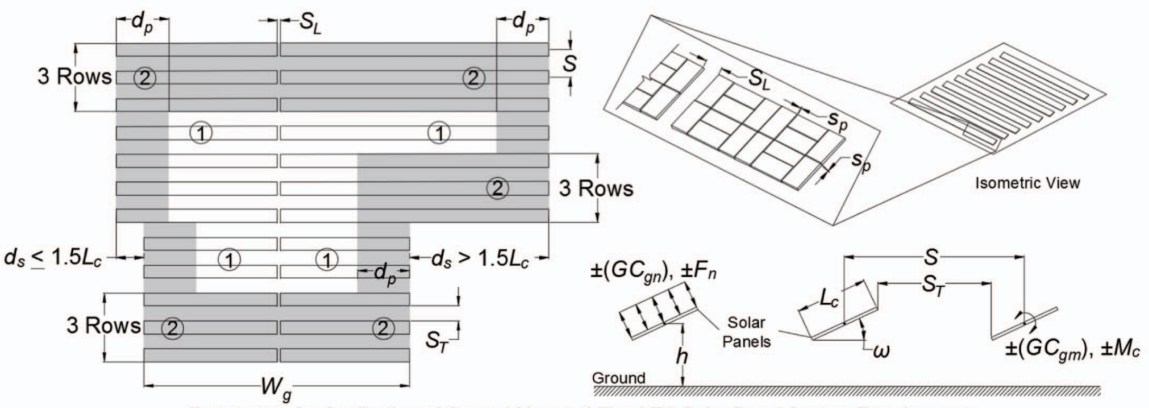
$$M_c = q_h K_d [\pm(GC_{gm})] A L_c \text{ (lb/ft)} \quad (29.4\text{-}9)$$

$$M_c = q_h K_d [\pm(GC_{gm})] A L_c \text{ (N/m)} \quad (29.4\text{-}9.SI)$$

where

$$GC_{gn} = [\pm(GC_{gn_{static}}) \pm (GC_{gn_{dynamic}})] \quad (29.4\text{-}10)$$

$$GC_{gm} = [\pm(GC_{gm_{static}}) \pm (GC_{gm_{dynamic}})] \quad (29.4\text{-}11)$$



q_h = Velocity pressure for all surfaces evaluated at the mean height of the panel, h in lb/ft² (N/m²);
K_d = Directionality Factor; see Section 26.6
$(GC_{gn_{static}})$ = Static net pressure coefficient, as determined from Figure 29.4-10;
$(GC_{gm_{dynamic}})$ = Dynamic net pressure coefficient, as determined from Figure 29.4-11, and shall be applied with the sign that yields the most adverse load effect;
$(GC_{gn_{static}})$ = Static moment coefficient, as determined from Figure 29.4-10;
$(GC_{gm_{dynamic}})$ = Dynamic moment coefficient, as determined from Figure 29.4-11, and shall be applied with the sign that yields the most adverse load effect; and
A = Effective wind area of element, ft² (m²).

Interior shielded Zone 1 and exterior perimeter Zone 2 shall be designed and designated, as shown in Figure 29.4-9.
For arrays with $0.20 \leq (L_c/S) < 0.25$, all rows shall be designed using Zone 2 static and dynamic coefficients.
For all locations, K_{zt} shall be determined per Equation (26.8-1). Where K_{zt} exceeds 1.0 per Equation (26.8-1), the static and dynamic coefficients for the Zone 2 shall be used throughout the entire array.

29.4.5.3 Design Support Posts and Foundations The support posts and foundations shall be designed for the simultaneous

@seismicisolation

Diagrams

Parameters for Application of Ground-Mounted Fixed-Tilt Solar Panel System Requirements

Notation

d_p = horizontal distance of Zone 2 from row end, ft (m); $d_p = 4L_c$ or 30 ft (9.1 m), whichever is smaller.

d_s = horizontal offset between adjacent rows with staggered row ends, ft (m);

1. Where an open area for access and/or clearance purposes exceeds a distance equal to $0.25L_c$ in the longitudinal direction or $2S$ in the transverse direction, a new Zone 2 is formed where the array meets it.
2. Where $d_s > 1.5L_c$, the Zone 2 width shall be increased to d_s in the longitudinal direction.
3. The Zone 2 width shall always be three rows in the transverse direction.

Figure 29.4-9. Parameters for application of ground-mounted fixed-tilt solar panel system requirements.

application of the design force, F_n, and design moment, M_c. The design value used for the horizontal component of F_n shall not be less than 0.1 times the vertical component of F_n.

29.4.5.4 Reduced Frequency for Ground-Mounted Solar Panel Systems The reduced frequency, N_s, for ground-mounted solar panel systems shall be determined by Equation (29.4-12)

$$N_s = 0.682nL_c/V \qquad (29.4\text{-}12)$$

$$N_s = nL_c/V \qquad (29.4\text{-}12.\text{SI})$$

where n is the lowest natural frequency of the mode of interest (moment or bending), Hz, and V is the basic wind speed mi/h (m/s).

29.5 PARAPETS

Wind loads on parapets are specified in Section 27.3.4 for buildings of all heights designed using the Directional Procedure and in Section 28.3.4 for low-rise buildings designed using the Envelope Procedure.

29.6 ROOF OVERHANGS

Wind loads on roof overhangs are specified in Section 27.3.3 for buildings of all heights designed using the Directional Procedure and in Section 28.3.5 for low-rise buildings designed using the Envelope Procedure.

29.7 MINIMUM DESIGN WIND LOADING

The design wind force for other structures shall be not less than 16 lb/ft^2 (0.77 kN/m^2) multiplied by the area, A_f.

29.8 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

The following consensus standards and other documents shall be considered part of this standard and are referenced in this chapter.

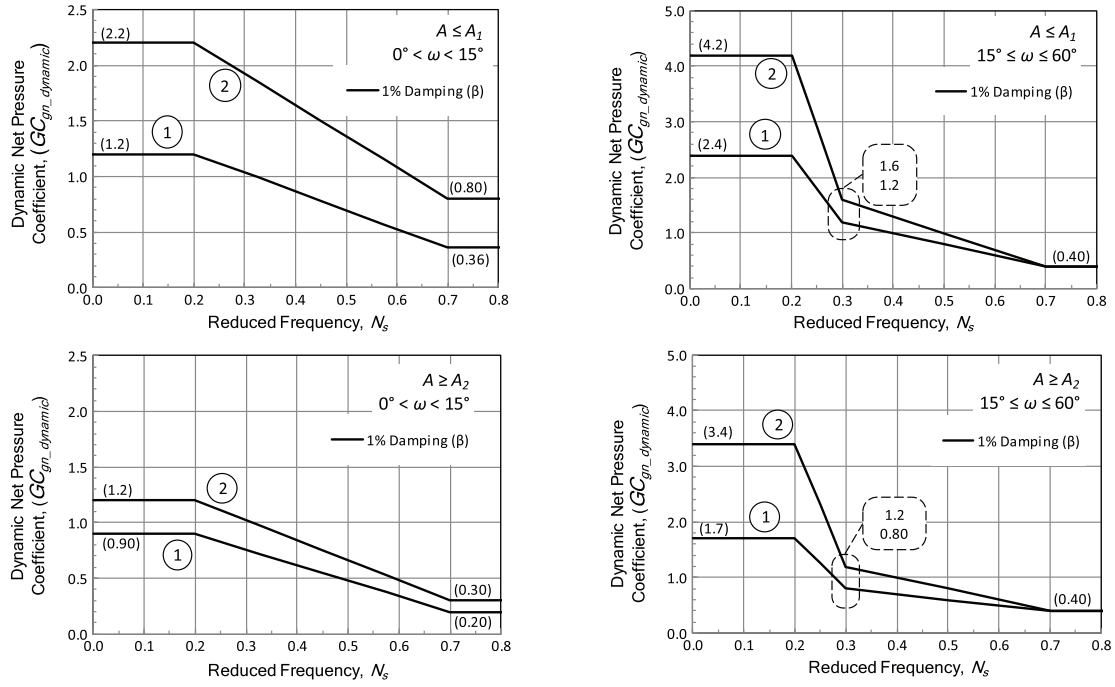
@seismicisolation

Static Net Pressure Coefficients for Zones 1 and 2 (GC_{gn_static})

Static Moment Coefficients for Zones 1 and 2 (GC_{gn_static})



Notes

1. Linear interpolation shall be permitted for values of ω between 5 and 15 degrees.
2. (GC_{gn}) denotes net pressures (contributions from top and bottom surfaces of the solar panels); plus and minus signs signify forces acting toward and away from the panels, respectively; each structural element shall be designed to with stand the worst structural effects produced by these two load cases.
3. (GC_{gn}) denotes moments about the center-of-plane of the panels (contributions from top and bottom surfaces of the solar panels) that comprise the full chord length (L_c); positive coefficients denote moments acting in a counter clockwise direction (see Figure 29.4-9), whereas negative coefficients denote moments acting in a clockwise direction; each structural element shall be designed to with stand the worst structural effects produced by these two load cases.

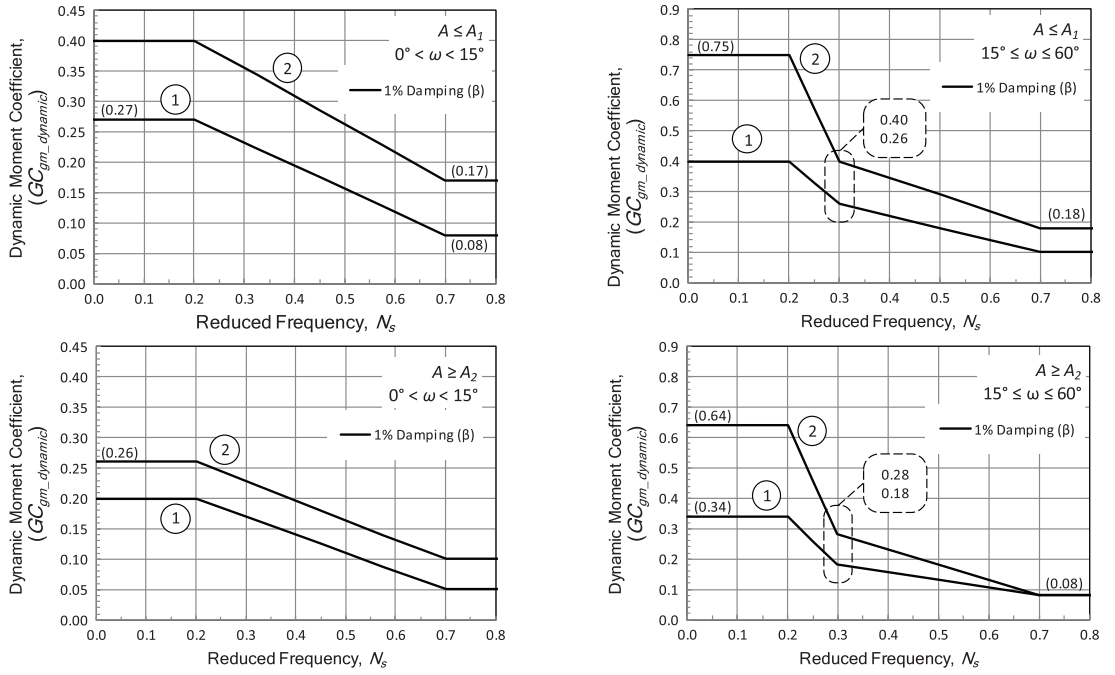


Figure 29.4-10. Design wind loads: static wind load coefficients for ground-mounted fixed-tilt solar panel systems.

@seismicisolation

Dynamic Net Pressure Coefficients for Zones 1 and 2 ($GC_{gn_dynamic}$)

Dynamic Moment Coefficients for Zones 1 and 2 ($GC_{gn_dynamic}$)

Notation

$A_1 = 4L_c^2$ or 500 ft^2 (46.5 m^2), whichever is smaller.
$A_2 = 15L_c^2$ or 1,000 ft^2 (92.9 m^2), whichever is smaller.
β = damping ratio (% of critical) in mode of interest.

Notes

1. Dynamic coefficients at a damping ratio, β, other than 1% damping (0.01) shall be calculated by multiplying the coefficients in this figure by $\sqrt{(0.01/\beta)}$, where $\beta \le 0.05$.
2. Linear interpolation for intermediate values of effective wind area, A, shall be permitted.

CHAPTER 30
WIND LOADS: COMPONENTS AND CLADDING

30.1 SCOPE

30.1.1 Building Types This chapter applies to the determination of wind pressures on components and cladding (C&C) on buildings.

1. Part 1 is applicable to an enclosed, partially enclosed, or partially open
   - Low-rise building (see definition in Section 26.2); or
   - Building with $h \leq 60$ ft (18.3 m).

   The building has a flat roof, gable roof, multispan gable roof, hip roof, monoslope roof, stepped roof, or sawtooth roof, and the wind pressures are calculated from a wind pressure equation.
2. Part 2 is applicable to an enclosed, partially enclosed, or partially open
   - Building with $h > 60$ ft (18.3 m).

   The building has a flat roof, pitched roof, gable roof, hip roof, mansard roof, arched roof, or domed roof, and the wind pressures are calculated from a wind pressure equation.
3. Part 3 is applicable to an open building of all heights that has a pitched free roof, monoslope free roof, or troughed free roof.
4. Part 4 is applicable to building appurtenances such as roof overhangs, parapets, and rooftop equipment.
5. Part 5 is applicable to non-building structures – circular bins, silos, and tanks; rooftop solar panels and roof pavers.
   - Circular bins, silos, and tanks with $h \leq 120$ ft (38.6 m);
   - Rooftop solar panels: Buildings of all heights with flat roofs or gable or hip roofs with roof slopes less than or equal to 7 degrees; and
   - Roof pavers: Buildings of all heights with roof slopes less than or equal to 7 degrees.

30.1.2 Conditions A building that has design wind loads determined in accordance with this chapter shall comply with all of the following conditions:

1. The building is a regular-shaped building as defined in Section 26.2; and
2. The building does not have response characteristics that make it subject to across-wind loading, vortex shedding, or instability caused by galloping or flutter; nor does it have a site location for which channeling effects or buffeting in the wake of upwind obstructions warrant special consideration.

30.1.3 Limitations The provisions of this chapter take into consideration the load magnification effect caused by gusts in resonance with along-wind vibrations of flexible buildings. The loads on buildings that do not meet the requirements of Section 30.1.2 or that have unusual shapes or response characteristics shall be determined using recognized literature documenting such wind load effects or shall use the wind tunnel procedure specified in Chapter 31.

30.1.4 Shielding There shall be no reductions in velocity pressure caused by apparent shielding afforded by buildings and other structures or terrain features.

30.1.5 Air-Permeable Cladding Design wind loads determined from Chapter 30 shall be used for air-permeable claddings, including modular vegetative roof assemblies, unless approved test data or recognized literature demonstrates lower loads for the type of air-permeable cladding being considered.

30.2 GENERAL REQUIREMENTS

30.2.1 Wind Load Parameters Specified in Chapter 26 The following wind load parameters are specified in Chapter 26:

- Basic wind speed, V (Section 26.5),
- Wind directionality factor, K_d (Section 26.6),
- Exposure category (Section 26.7),
- Topographic factor, K_{zt} (Section 26.8),
- Ground elevation factor, K_e (Section 26.9),
- Velocity pressure exposure coefficient, K_z or K_h (Section 26.10.1); Velocity pressure, q_z (Section 26.10.2),
- Gust-effect factor (Section 26.11),
- Enclosure classification (Section 26.12), and
- Internal pressure coefficient, (GC_{pi}) (Section 26.13).

30.2.2 Minimum Design Wind Pressures The design wind pressure for C&C of buildings shall not be less than a net pressure of 16 lb/ft^2 (0.77 kN/m^2) acting in either direction normal to the surface.

30.2.3 Tributary Areas Greater than 700 ft^2 (65 m^2) C&C elements with tributary areas greater than 700 ft^2 (65 m^2) shall be permitted to be designed using the provisions for main wind force resisting systems.

30.2.4 External Pressure Coefficients Combined gust-effect factor and external pressure coefficients for C&C, (GC_p), are given in the figures associated with this chapter. The pressure coefficient values and gust-effect factor shall not be separated.

@seismicisolation
@seismicisolation

PART 1: LOW-RISE BUILDINGS

User Note: Use Part 1 of Chapter 30 to determine wind pressures on C&C of *enclosed, partially enclosed, or partially open low-rise buildings* that have roof shapes as specified in the applicable figures. The provisions in Part 1 are based on the Envelope Procedure, with *wind pressures calculated using the specified equation* as applicable to each building surface. For buildings for which these provisions are applicable, this method generally yields the lowest wind pressures of all analytical methods contained in this standard.

30.3 BUILDING TYPES

The provisions of Section 30.3 are applicable to an enclosed, partially enclosed, or partially open

- Low-rise building (see definition in Section 26.2); or
- Building with $h \le 60$ ft (18.3 m).

The building has a flat roof, gable roof, multispan gable roof, hip roof, monoslope roof, stepped roof, or sawtooth roof. The steps required for the determination of wind loads on C&C for these building types are shown in Table 30.3-1.

30.3.1 Conditions For the determination of the design wind pressures on the C&C using the provisions of Section 30.3.2, the conditions indicated on the selected figure(s) shall be applicable to the building under consideration.

30.3.2 Design Wind Pressures Design wind pressures on C&C elements of low-rise buildings and buildings with $h \le 60$ ft (18.3 m) shall be determined from the following equation:

$$p = q_h K_d [(GC_p) - (GC_{pi})] (\text{lb/ft}^2) \quad (30.3\text{-}1)$$

$$p = q_h K_d [(GC_p) - (GC_{pi})] (\text{N/m}^2) \quad (30.3\text{-}1.\text{SI})$$

where

q_h = Velocity pressure evaluated at mean roof height h as defined in Section 26.10;
K_d = Wind directionality factor, see Section 26.6; and
(GC_p) = External pressure coefficients given in

- Figure 30.3-1 (walls),
- Figures 30.3-2A–G (flat roofs, gable roofs, and hip roofs) and 30.5.2 (pitched free roofs),
- Figure 30.3-3 (stepped roofs),
- Figure 30.3-4 (multispan gable roofs),
- Figsure 30.3-5A–B (monoslope roofs),
- Figure 30.3-6 (sawtooth roofs),
- Figure 30.3-7 (domed roofs),
- Figure 30.3-8 (arched roofs),
- Figure 30.3-2A (bottom surfaces of elevated buildings).

(GC_{pi}) = Internal pressure coefficient given in Table 26.13-1.

30.3.2.1 Bottom Horizontal Surface of Elevated Buildings. Design wind pressures for C&C elements on the bottom flat horizontal surface of elevated buildings shall be determined using the roof pressure coefficients from Figure 30.3-2A with the following modifications:

1. h_B shall be the height above grade of the bottom surface of the elevated building, as depicted in Figure 30.3-1A. The value of h shall equal h_B for determining zone dimensions from Figure 30.3-2A. For elevated buildings with a flat bottom horizontal building surface and situated on a slope, h_B shall be taken as the maximum height between the slope and the bottom of the elevated building.
2. Areas of the horizontal surface above partially enclosed spaces and areas extending a_B perpendicular to walls beneath the elevated building with plan dimension greater than 4 ft (1.2 m), as shown in the shaded regions in Figure 30.3-1A, shall be designed to resist positive pressures equal to the Zone 4 wall pressures obtained using Figure 30.3-1. The value of a_B shall equal 0.4 h_B or the width of the wall, whichever is smaller for determining zone dimensions from Figure 30.3-1A.

The loading convention shall denote downward loading on the bottom surface with negative pressure coefficients and upward loading on the bottom surface with positive pressure coefficients.

EXCEPTION: The provisions of Section 30.3.2.1 do not apply to buildings with $h_B < 2$ ft (0.61 m).

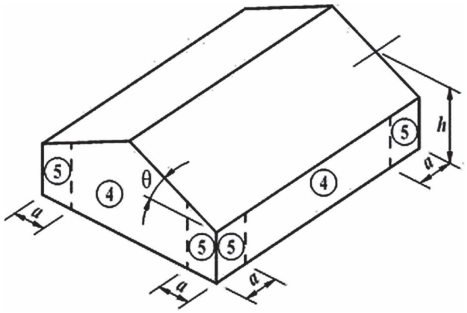
Table 30.3-1. Steps to Determine C&C Wind Loads for Enclosed, Partially Enclosed, and Partially Open Low-Rise Buildings.

Step 1: Determine risk category; see Table 1.5-1.
Step 2: Determine the basic wind speed, V, for applicable risk category; see Figure. 26.5-1.
Step 3: Determine the wind load parameters:

- Wind directionality factor, K_d; see Section 26.6 and Table 26.6-1.
- Exposure Category B, C, or D; see Section 26.7.
- Topographic factor, K_{zt}; see Section 26.8 and Figure 26.8-1.
- Ground elevation factor, K_e; Section 26.9 and Table 26.9-1.
- Enclosure classification; see Section 26.12.
- Internal pressure coefficient, (GC_{pi}); see Section 26.13 and Table 26.13-1.

Step 4: Determine velocity pressure exposure coefficient, K_h; see Table 26.10-1.
Step 5: Determine velocity pressure, q_h, Equation (26.10-1).
Step 6: Determine external pressure coefficient, (GC_p):

- Walls; see Figure 30.3-1.
- Flat roofs, gable roofs, hip roofs; see Figure 30.3-2.
- Stepped roofs; see Figure 30.3-3.
- Multispan gable roofs; see Figure 30.3-4.
- Monoslope roofs; see Figure 30.3-5.
- Sawtooth roofs; see Figure 30.3-6.
- Domed roofs; see Figure 30.3-7.
- Arched roofs; see Figure 30.3-8.
- Bottom horizontal surface of elevated buildings; see Section 30.3.2.1.



Step 7: Calculate wind pressure, p; Equation (30.3-1).

PART 2: BUILDINGS WITH $h > 60$ ft [$(h > 18.3$ m)]

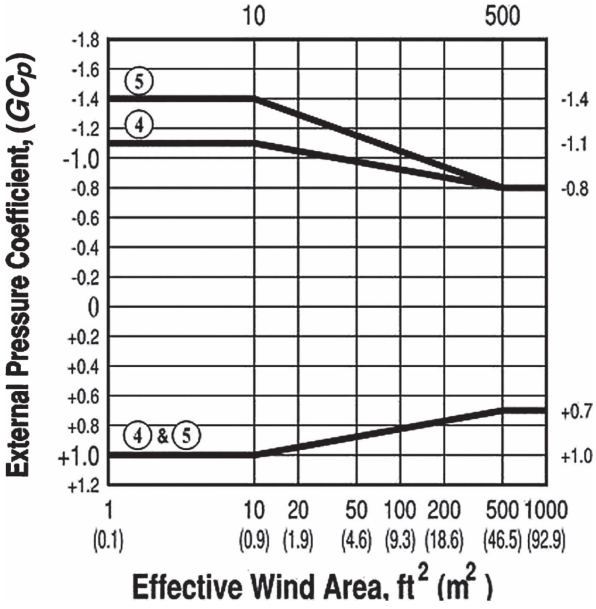
User Note: Use Part 2 of Chapter 30 for determining wind pressures for C&C of *enclosed, partially enclosed, or partially open buildings with* $h \le 60$ ft (18.3 m) that have roof shapes as specified in the applicable figures. These provisions are based on the Directional Procedure with *wind pressures calculated from the specified equation* applicable to each building surface.

@seismicisolation

Diagram

ELEVATION

Notation



a = 10% of least horizontal dimension or 0.4h, whichever is smaller, but not less than either 4% of least horizontal dimension or 3 ft (0.9 m).

Exception: For buildings with θ = 0° to 7° and a least horizontal dimension greater than 300 ft (90 m), dimension a shall be limited to a maximum of 0.8h.

h = Mean roof height, ft (m), except that eave height shall be used for θ ≤ 10°.

θ = Angle of plane of roof from horizontal, degrees.

External Pressure Coefficient, (GC_p) - Walls

Notes

1. Vertical scale denotes (GCp) to be used with q_h.
2. Horizontal scale denotes effective wind area A, ft^2 (m^2).
3. Plus and minus signs signify pressures acting toward and away from the surfaces, respectively.
4. Each component shall be designed for maximum positive and negative pressures.
5. Values of (GCp) for walls shall be reduced by 10% when θ ≤ 10°.

Figure 30.3-1. Components and cladding, $h \leq 60$ ft (18.3 m): external pressure coefficients (GC_p) for enclosed, partially enclosed, and partially open buildings—walls.

@seismicisolation

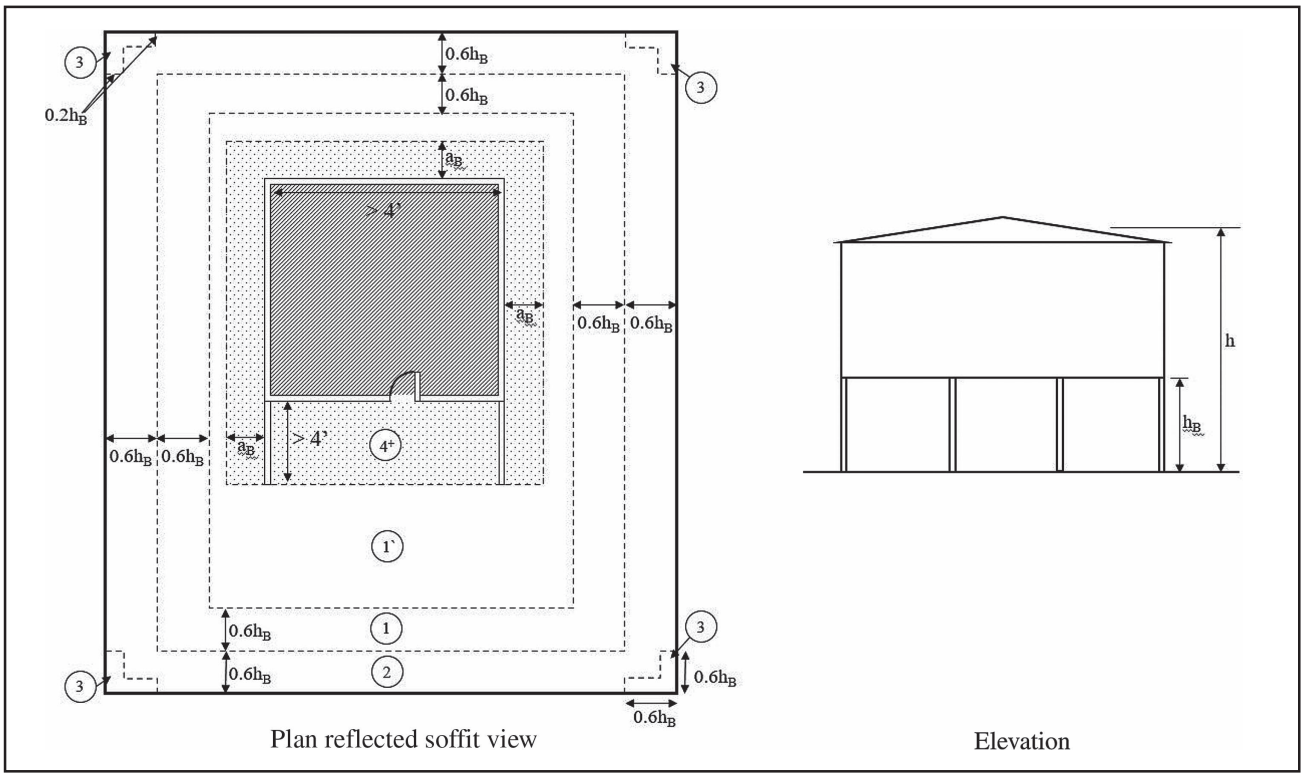


Figure 30.3-1A. Components and cladding [$h \leq 60$ ft (18.3 m)]: external pressure coefficient zones for enclosed, partially enclosed, and partially open elevated buildings with partially enclosed spaces and areas beneath the elevated building—bottom horizontal surface of elevated buildings.

30.4 BUILDING TYPES

The provisions of Section 30.4 are applicable to an enclosed, partially enclosed, or partially open building with a mean roof height [$h > 60$ ft ($h > 18.3$ m)] with a flat roof, pitched roof, gable roof, hip roof, mansard roof, arched roof, or domed roof. The steps required for the determination of wind loads on C&C for these building types are shown in Table 30.4-1.

30.4.1 Conditions For the determination of the design wind pressures on the C&C using the provisions of Section 30.4.2, the conditions indicated on the selected figure(s) shall be applicable to the building under consideration.

30.4.2 Design Wind Pressures Design wind pressures on C&C for all buildings with [$h > 60$ ft ($h < 18.3$ m)] shall be determined from the following equation:

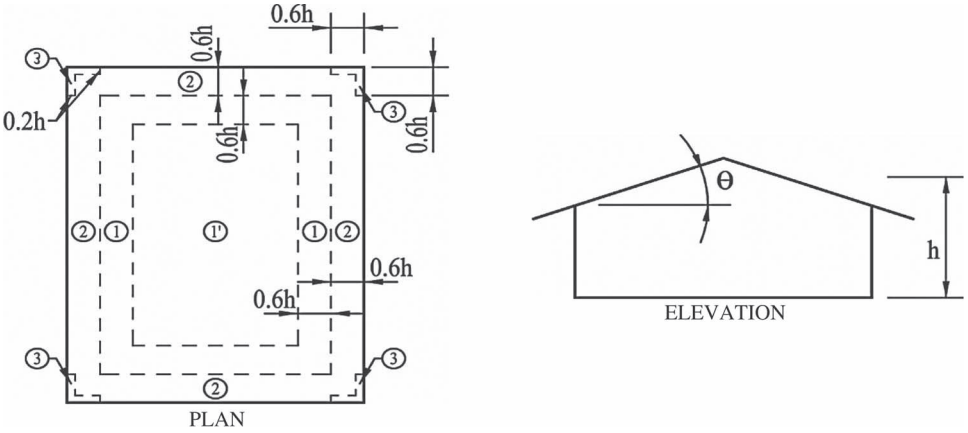
$$p = qK_d(GC_p) - q_iK_d(GC_{pi})(\text{lb/ft}^2) \quad (30.4\text{-}1)$$

$$p = qK_d(GC_p) - q_iK_d(GC_{pi})(\text{N/m}^2) \quad (30.4\text{-}1.\text{SI})$$

where

$q = q_z$ For windward walls calculated at height z above the ground;
$q = q_h$ For leeward walls, sidewalls, and roofs evaluated at height h;
K_d = Wind directionality factor, see Section 26.6;
$q_i = q_h$ For windward walls, sidewalls, leeward walls, and roofs of enclosed and partially open buildings and for negative internal pressure evaluation in partially enclosed buildings;

Table 30.4-1. Steps to determine C&C wind loads for enclosed, partially enclosed, or partially open building with $h > 60$ ft ($h > 18.3$ m)].



Step 1: Determine risk category; see Table 1.5-1.
Step 2: Determine the basic wind speed, V, for applicable risk category; see Figure 26.5-1.
Step 3: Determine wind load parameters:
- Wind directionality factor, K_d; see Section 26.6 and Table 26.6-1.
- Exposure Category B, C, or D; see Section 26.7.
- Topographic factor.
- K_{zt}; see Section 26.8 and Figure 26.8-1.
- Ground elevation factor, K_e; see Section 26.9 and Table 26.9-1.
- Enclosure classification; see Section 26.12.
- Internal pressure coefficient, GC_{pi}; see Section 26.13 and Table 26.13-1.

Step 4: Determine velocity pressure exposure coefficient, K_z or K_h; see Table 26.10-1.
Step 5: Determine velocity pressure, q_h, Equation (26.10-1).
Step 6: Determine external pressure coefficient (GC_p):
- Walls and flat roofs ($\theta < 10°$); see Figure 30.4-1.
- Gable and hip roofs; see Figure 30.3-2 per Note 6 of Figure 30.4-1.
- Arched roofs; see Figure 30.3-8.
- Domed roofs; see Figure 30.3-7.
- Bottom horizontal surface of elevated buildings; see Section 30.4.2.1.

Step 7: Calculate wind pressure, p, Equation (30.4-1).

External Pressure	Negative Pressures	Positive Pressures	Positive Pressures
θ, degrees	0–90	0–60	61–90
(GC_p)	–0.9	+0.9	+0.5

Notes

1. Values denote (GC_p) to be used with $q_{(h_D+f)}$ where $h_D + f$ is the height at the top of the dome.
2. Plus and minus signs signify pressures acting toward and away from the surfaces, respectively.
3. Each component shall be designed for the maximum positive and negative pressures.
4. Values apply to $0 \le h_D/D \le 0.5$, $0.2 \le f/D \le 0.5$.
5. θ = 0 degrees on dome springline, θ = 90 degrees at dome center top point. f is measured from springline to top.

Figure 30.3-7. Components and cladding (all heights): external pressure coefficients, (GC_p), for enclosed, partially enclosed, and partially open buildings and structures—domed roofs.

$q_i = q_z$ For positive internal pressure evaluation in partially enclosed buildings where height z is defined as the level of the highest opening in the building that could affect the positive internal pressure. For positive internal pressure evaluation, q_i may conservatively be evaluated at height $h(q_i = q_h)$;

(GC_p) = External pressure coefficients given in

- Figure 30.4-1 for walls and flat roofs,
- Figure 30.3-8 for arched roofs,
- Figure 30.3-7 for domed roofs,
- Note 6 of Figure 30.4-1 for other roof angles and geometries; and
- Figure 30.4-1 for bottom surfaces of elevated buildings.

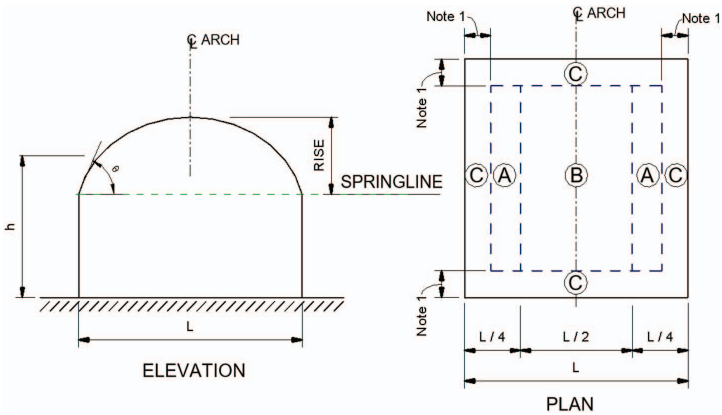
(GC_{pi}) = Internal pressure coefficient given in Table 26.13-1.

q and q_i shall be evaluated using exposure as defined in Section 26.7.3.

30.4.2.1 Bottom Horizontal Surface of Elevated Buildings Design wind pressures for C&C elements on the bottom flat horizontal surface of elevated buildings shall be determined using the roof pressure coefficients from Figure 30.4-1 with the following modifications:

1. The velocity pressure, q, used in Equation 30.4-1 shall be calculated at a height equal to the height above grade of the bottom horizontal surface plus 25% of the height of the elevated building above the horizontal bottom surface, calculated as $[h_B + 0.25(h - h_B)]$. For elevated buildings with a flat bottom horizontal building surface and situated on a slope, h_B shall be taken as the maximum height between the slope and the bottom of the elevated building.
2. Areas of the horizontal surface above partially enclosed spaces and areas extending a distance a_B perpendicular to walls with plan dimension greater than 4 ft (1.2 m), as shown by the shaded regions in Figure 30.4-1A, shall be designed to resist positive pressures equal to the Zone 4 wall pressures obtained using Figure 30.4-1. The value of a_B shall equal 0.4 h_B or the width of the wall, whichever is smaller, for determining zone dimensions from Figure 30.4-1A.

The loading convention shall denote downward loading on the bottom surface with negative pressure coefficients and upward loading on the bottom surface with positive pressure coefficients.



EXCEPTION: In buildings with a mean roof height h greater than 60 ft (18.3 m) and less than 90 ft (27.4 m), Figures 30.3-1 through 30.3-6 shall be permitted to be used if the mean roof height h does not exceed least horizontal dimension.

PART 3: OPEN BUILDINGS

User Note: Use Part 3 of Chapter 30 for determining wind pressures for C&C of *open buildings* that have pitched, monoslope, or troughed roofs. These provisions are based on the Directional Procedure with *wind pressures calculated from the specified equation* applicable to each roof surface.

@seismicisolation

Diagrams

Notation

L = Horizontal dimension of building, ft (m), measured normal to ridge.

r = Rise-to-span ratio = 'rise'/L.

h = Roof height as defined in Chapter 26 for roof angle θ.

θ = Angle of plane of roof from horizontal, in degrees, measured at eave.

External Pressure Coefficient, GC_p

Conditions	Rise-to-Span Ratio, r	(GC_p)	
		Zone A	Zone B
Roof on elevated structure	$0 < r < 0.2$	–1.08	–0.84–1.2r
	$0.2 \le r < 0.3$	1.8r–0.36 7.2r–2.52 –0.6	–0.84–1.2r
	$0.3 \le r \le 0.6$	3.3r–0.84 –0.6	–0.84–1.2r
Roof springing from ground level	$0 < r \le 0.6$	1.68r –0.6	–0.84–1.2r

Notes

1. At roof perimeter Zone C, use the roof zones (Zone 2 and 3) and external pressure coefficients in Fig. 30.3-2A, B, C, and D with "θ" based on springline slope. In the case of Fig. 30.3-2A, use 0.6h as the size of the roof perimeter Zone C. For roof Zones A and B, use external pressure coefficients shown in this table.
2. Plus and minus signs signify pressures acting toward and away from the surfaces, respectively.
3. Where multiple values of (GC_p) are listed, the roof zone is subjected to either positive or negative pressures and the structure shall be designed for all conditions.

Figure 30.3-8. Components and cladding (all heights): external pressure coefficients, (GC_p), for enclosed, partially enclosed, and partially open buildings and structures—arched roofs.

@seismicisolation

30.5 BUILDING TYPES

The provisions of Section 30.5 are applicable to an open building of all heights that has a pitched free roof, monosloped free roof, or troughed free roof. The steps required for the determination of wind loads on C&C for these building types is shown in Table 30.5-1.

30.5.1 Conditions For the determination of the design wind pressures on C&Cs using the provisions of Section 30.5.2, the conditions indicated on the selected figure(s) shall be applicable to the building under consideration.

30.5.2 Design Wind Pressures The net design wind pressure for component and cladding elements of open buildings of all heights with monoslope, pitched, and troughed roofs shall be determined by the following equation:

$$p = q_h K_d G C_N \tag{30.5-1}$$

where

q_h = Velocity pressure evaluated at mean roof height h using the exposure as defined in Section 26.7.3 that results in the highest wind loads for any wind direction at the site; and
K_d = Wind directionality factor, see Section 26.6;
G = Gust-effect factor from Section 26.11; and
C_N = Net pressure coefficient given in

- Figure 30.5-1 for monosloped roof,
- Figure 30.5-2 for pitched roof, and
- Figure 30.5-3 for troughed roof.

Net pressure coefficients, C_N, include contributions from top and bottom surfaces. All load cases shown for each roof angle shall be investigated. Plus and minus signs signify pressure acting toward and away from the top surface of the roof, respectively.

PART 4: BUILDING APPURTENANCES, ROOFTOP STRUCTURES AND EQUIPMENT

User Note: Use Part 4 of Chapter 30 for determining wind pressures for C&C on roof overhangs or parapets of buildings. These provisions are based on the Directional Procedure with *wind pressures calculated from the specified equation* applicable to each roof overhang or parapet surface.

Table 30.5-1. Steps to Determine C&C Wind Loads for Open Buildings.

Step 1: Determine risk category; see Table 1.5-1.
Step 2: Determine the basic wind speed, V, for applicable risk category; see Figure 26.5-1.
Step 3: Determine wind load parameters:
- Wind directionality factor, K_d, see Section 26.6 and Table 26.6-1.
- Exposure Category B, C, or D; see Section 26.7.
- Topographic factor, K_{zt}; see Section 26.8 and Figure 26.8-1.
- Ground elevation factor, K_e; see Section 26.9 and Table 26.9-1.
- Gust-effect factor, G; see Section 26.11.

Step 4: Determine velocity pressure exposure coefficient, K_z or K_h; see Table 26.10-1.
Step 5: Determine velocity pressure, q_h, Equation (26.10-1).
Step 6: Determine net pressure coefficients, C_N:
- Monoslope roof; see Figure 30.5-1.
- Pitched roof; see Figure 30.5-2.
- Troughed roof; see Figure 30.5-3.

Step 7: Calculate wind pressure, p, Equation (30.5-1).

30.6 PARAPETS

The design wind pressure for C&C elements of parapets for all building types and heights shall be determined from the following equation:

$$p = q_p K_d((GC_p) - (GC_{pi})) \tag{30.6-1}$$

where

q_p = Velocity pressure evaluated at the top of the parapet;
K_d = Wind directionality factor, see Section 26.6;
(GC_p) = External pressure coefficient given in

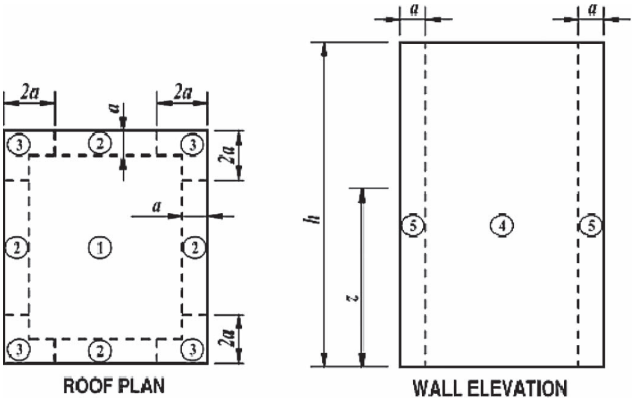
- Figure 30.3-1 for walls with $h \leq 60$ ft (18.3 m);
- Figure 30.3-2A–C for flat roofs, gable roofs, and hip roofs;
- Figure 30.3-3 for stepped roofs;
- Figure 30.3-4 for multispan gable roofs;
- Figure 30.3-5A–B for monoslope roofs;
- Figure 30.3-6 for sawtooth roofs;
- Figure 30.3-7 for domed roofs of all heights;
- Figure 30.4-1 for walls and flat roofs with $h > 60$ ft (18.3 m);
- Figure 30.3-8 for arched roofs.

(GC_{pi}) = Internal pressure coefficient from Table 26.13-1, based on the porosity of the parapet envelope.

Two load cases from Figure 30.6-1 shall be considered:

- *Load Case A:* Windward parapet shall consist of applying the applicable positive wall pressure from Figure 30.3-1 [$h \leq 60$ft ($h \leq 18.3m$)] or Figure 30.4-1 [$h > 60$ft ($h > 18.3m$)] to the

Table 30.6-1. Steps to Determine C&C Wind Loads for Parapets.

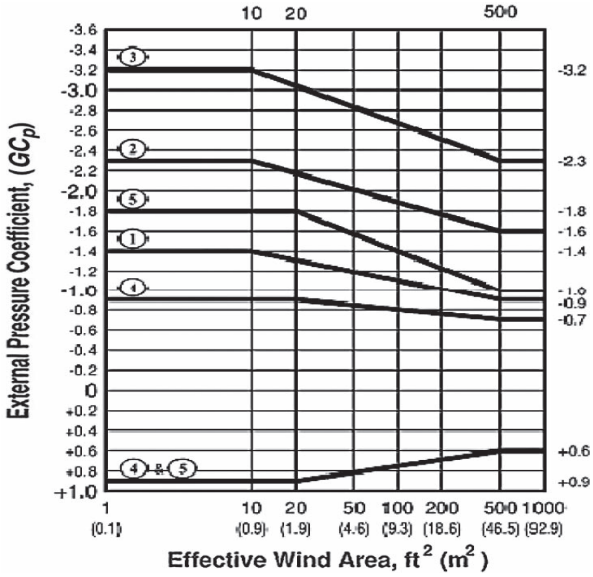


Step 1: Determine risk category of building; see Table 1.5-1.
Step 2: Determine the basic wind speed, V, for applicable risk category; see Figure. 26.5-1.
Step 3: Determine wind load parameters:
- Wind directionality factor, K_d; see Section 26.6 and Table 26.6-1.
- Exposure Category B, C, or D; see Section 26.7.
- Topographic factor, K_{zt}; see Section 26.8 and Figure 26.8-1.
- Ground elevation factor, K_e; see Section 26.9 and Table 26.9-1.
- Enclosure classification; see Section 26.12.
- Internal pressure coefficient (GC_{pi}); see Section 26.13 and Table 26.13-1.

Step 4: Determine velocity pressure exposure coefficient, K_h, at top of the parapet; see Table 26.10-1.
Step 5: Determine velocity pressure, q_p, at the top of the parapet using Equation (26.10-1).
Step 6: Determine external pressure coefficient for wall and roof surfaces adjacent to parapet, (GC_p):
- Walls with $h \leq 60ft$ (18.3 m); see Figure 30.3-1.
- Flat, gable, and hip roofs; see Figure 30.3-2A–I.
- Stepped roofs; see Figure 30.3-3.
- Multispan gable roofs; see Figure 30.3-4.
- Monoslope roofs; see Figure 30.3-5A–B.
- Sawtooth roofs; see Figure 30.3-6.
- Domed roofs of all heights; see Figure 30.3-7.
- Walls and flat roofs with $h > 60ft$ ($h > 18.3m$); see Figure 30.4-1.
- Arched roofs; see Figure 30.3-8.

Step 7: Calculate wind pressure, p, using Equation (30.6-1) on windward and leeward face of parapet, considering two load cases (Case A and Case B) as shown in Figure 30.6-1.

@seismicisolation



Diagrams

Notation

a = 10% of least horizontal dimension, but not less than 3 ft (0.9 m).
h = Mean roof height, ft (m), except that eave height shall be used for $\theta \le 10°$.
z = Height above ground, ft (m).
θ = Angle of plane of roof from horizontal, degrees.

External Pressure Coefficients

Notes

1. Vertical scale denotes (GCp) to be used with appropriate q_z or q_h.
2. Horizontal scale denotes effective wind area A, ft^2 (m^2)
3. Plus and minus signs signify pressures acting toward and away from the surfaces, respectively.
4. Use q_z with positive values of (GCp) and q_h with negative values of (GCp).
5. Each component shall be designed for maximum positive and negative pressures.
6. Coefficients are for roofs with angle $\theta \le 7°$. For other roof angles and geometry, use (GCp) values from Fig. 30.3-2A–2I and Fig. 30.3-5A,5B and attendant q_h based on exposure defined in Section 26.7.
7. If a parapet equal to or higher than 3 ft (0.9 m) is provided around the perimeter of the roof with $\theta \le 10°$, Zone 3 shall be treated as Zone 2.

Figure 30.4-1. Components and cladding, part 2 [h > 60ft (h > 18.3m)]: external pressure coefficients, (GC_p), for enclosed, partially enclosed, partially open buildings—walls and roofs.

@seismicisolation

Diagrams

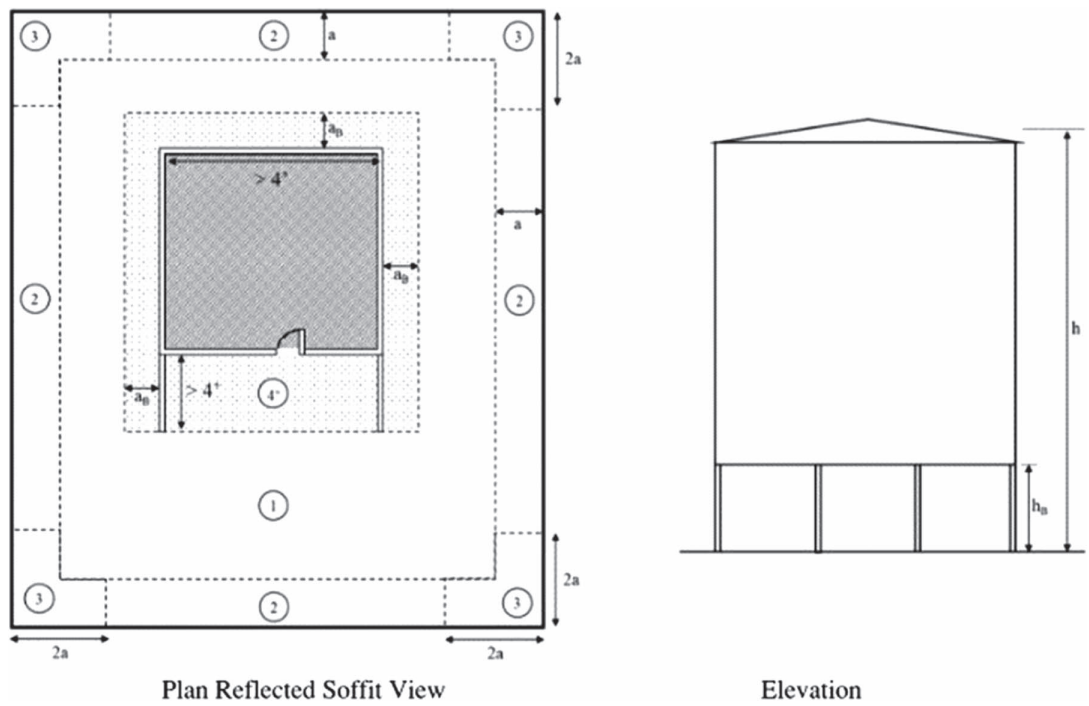


Figure 30.4-1A. Components and cladding, part 3 [$h > 60$ ft ($h > 18.3$ m)]: external pressure coefficient zones for enclosed, partially enclosed, and partially open elevated buildings with partially enclosed spaces and areas beneath the elevated building—bottom horizontal surface of elevated buildings.

windward surface of the parapet while applying the applicable negative edge or corner zone roof pressure from Figures 30.3-2A, B, or C, 30.3-3, 30.3-4, 30.3-5A or B, 30.3-6, 30.3-7, Figure 30.3-8, or Figure 30.4-1 [$h > 60$ft ($h > 18.3m$)] as applicable to the leeward surface of the parapet.

- *Load Case B:* Leeward parapet shall consist of applying the applicable positive wall pressure from Figure 30.3-1 [$h \leq 60$ft ($h \leq 18.3m$)] or Figure 30.4-1 [$h > 60$ft ($h > 18.3m$)] to the windward surface of the parapet, and applying the applicable negative wall pressure from Figure 30.3-1 [$h \leq 60$ft ($h \leq 18.3m$)] or Figure 30.4-1 [$h > 60$ft ($h > 18.3m$)] as applicable to the leeward surface. Edge and corner zones shall be arranged as shown in the applicable figures. (GC_p) shall be determined for appropriate roof angle and effective wind area from the applicable figures.

If internal pressure is present, both load cases should be evaluated under positive and negative internal pressure.

The steps required for the determination of wind loads on component and cladding of parapets are shown in Table 30.6-1.

30.7 ROOF OVERHANGS

The design wind pressure for roof overhangs of enclosed, partially enclosed, and partially open buildings of all heights shall be determined from the following equation:

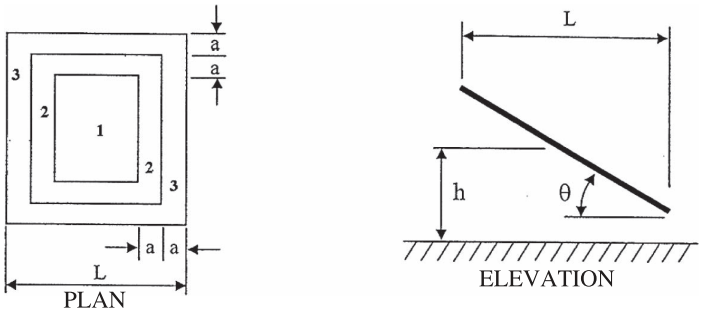
$$p = q_h K_d[(GC_p) - (GC_{pi})](\text{lb/ft}^2) \quad (30.7\text{-}1)$$

$$p = q_h K_d[(GC_p) - (GC_{pi})](\text{N/m}^2) \quad (30.7\text{-}1.\text{SI})$$

where

q_h = Velocity pressure from Section 26.10 evaluated at mean roof height h using exposure defined in Section 26.7.3;

K_d = Wind directionality factor; see Section 26.6;



(GC_p) = External pressure coefficient at the overhang, (GC_p), given in Figure 30.3-2A for gable roofs $\theta \leq 7°$ [$h \leq 60$ ft (18.3 m)], or calculated as the sum of the GC_p of the overhang's top and bottom surfaces determined by the applicable roof and wall external pressure coefficient GC_p figures. The GC_p of the overhang's top surface is the same as the applicable roof surface's GC_p; the GC_p of the overhang's bottom surface is the same as the adjacent wall's GC_p, adjusted for effective wind area.

(GC_{pi}) = Internal pressure coefficient given in Table 26.13-1.

The steps required for the determination of wind loads on C&C of roof overhangs are shown in Table 30.7-1.

Diagrams

Notes

Windward Parapet: Load Case A

1. Windward parapet pressure (p_1) is determined using the positive wall pressure (p_5) Zones 4 or 5 from the applicable figure.
2. Leeward parapet pressure (p_2) is determined using the negative roof pressure (p_7) Zones 2 or 3 from the applicable figure.

Leeward Parapet: Load Case B

1. Windward parapet pressure (p_3) is determined using the positive wall pressure (p_5) Zones 4 or 5 from the applicable figure.
2. Leeward parapet pressure (p_4) is determined using the negative wall pressure (p_6) Zones 2 or 3 from the applicable figure.

User Note: See Note 5 in Figure 30.3-2A and Note 7 in Figure 30.5-1 for reductions in component and cladding roof pressures when parapets 3 ft (0.9 m) or higher are present.

Figure 30.6-1. Components and cladding, part 4 (all building heights): parapet wind loads for all building types—parapet wind loads.

Table 30.7-1. Steps to Determine C&C Wind Loads for Roof Overhangs.

Step 1: Determine risk category of building; see Table 1.5-1.

Step 2: Determine the basic wind speed, V, for applicable risk category; see Fig. 26.5-1.

Step 3: Determine wind load parameters:

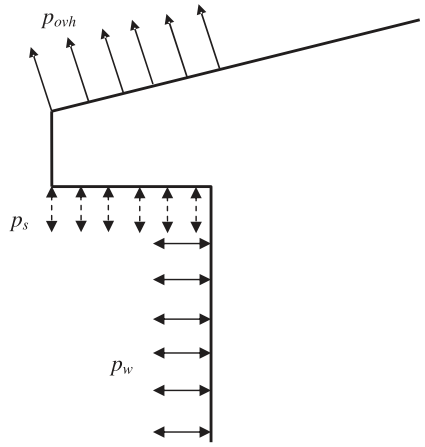
- Wind directionality factor, K_d; see Section 26.6 and Table 26.6-1.
- Exposure Category B, C, or D; see Section 26.7.
- Topographic factor, K_{zt}; see Section 26.8 and Figure 26.8-1.
- Ground elevation factor, K_e; see Section 26.9 and Table 26.9-1.
- Enclosure classification; see Section 26.12.
- Internal pressure coefficient (GC_{pi}); see Section 26.13 and Table 26.13-1.

Step 4: Determine velocity pressure exposure coefficient, K_h; see Table 26.10-1.

Step 5: Determine velocity pressure, q_h, at mean roof height h using Equation (26.10-1).

continues

Table 30.7-1 *(Continued)*. Steps to Determine C&C Wind Loads for Roof Overhangs.



Step 6: Determine the external pressure coefficient (GC_p) at the overhang, using Figure 30.3-2A for gable roofs $\theta \le 7°$ [$h \le 60$ ft (18.3 m)], or calculated as the sum of the GC_p coefficients on the overhang's top and bottom surfaces, as determined by the applicable roof and wall GC_p given in figures:

- Gable roofs $7° < \theta \le 45°$, hip roofs $\theta \le 45°$ [$h \le 60$ ft (18.3 m)]: see Figure 30.3-2B-G.
- Other roofs [$h \le 60$ ft (18.3 m)]: see Table 30.3-1 Step 6.
- Flat roofs $\theta \le 7°$ [$h > 60$ ft (18.3 m)]: see Figure 30.5-1.
- Gable and hip roofs [$h > 60$ ft (18.3 m)]: see Figure 30.5-1.
- Other roofs [$h > 60$ ft (18.3 m)]: see Table 30.5-1 Step 6.
- Walls [$h \le 60$ ft (18.3 m)]: see Figure 30.3-1.
- Walls [$h > 60$ ft (18.3 m)]: see Figure 30.5-1.

Step 7: Calculate wind pressure, p, using Equation (30.7-1); refer to Figure 30.7-1.

@seismicisolation

Diagrams

Notation

p_{ovh} = Net roof pressure on roof overhangs.
p_s = Pressure on roof overhang soffit.
p_w = Pressure on wall.

Notes

1. Net roof pressure, p_{ovh}, on roof overhangs is determined from interior, edge, or corner zones as applicable from figures.
2. Net pressure, p_{ovh}, from figures includes pressure contribution from top and bottom surfaces of roof overhang.
3. Positive pressure at roof overhang soffit p_s shall be taken as equal to the wall pressure p_w.

Figure 30.7-1. Components and cladding (all building heights): wind loading on roof overhangs for all building types—C&C wind loads on roof overhangs.

30.8 ROOFTOP STRUCTURES AND EQUIPMENT FOR BUILDINGS

The C&C pressure on each wall of the rooftop structure shall be equal to the lateral force determined in accordance with Section 29.4.1 divided by the respective wall surface area of the rooftop structure and shall be considered to act inward and outward. The C&C pressure on the roof shall be equal to the vertical uplift force determined in accordance with Section 29.4.1 divided by the horizontal projected area of the roof of the rooftop structure and shall be considered to act in the upward direction.

30.9 ATTACHED CANOPIES ON BUILDINGS

The design wind pressure for canopies attached to the walls of buildings shall be determined from the following equation:

$$p = q_h K_d (GC_p)(\text{lb/ft}^2) \quad (30.9\text{-}1)$$

$$p = q_h K_d (GC_p)(\text{N/m}^2) \quad (30.9\text{-}1.\text{SI})$$

where

q_h = Velocity pressure from Section 26.10 evaluated at mean roof height h using exposure defined in Section 26.7.3; and
K_d = Wind directionality factor; see Section 26.6; and
(GC_p) = Net pressure coefficients for attached canopies given in Figure 30.9-1A–B [buildings with $h < 60$ ft ($h < 18.3$ m)] and 30.9-2A-B [buildings with $h > 60$ ft ($h > 18.3$ m)] for contributions from both upper and lower surfaces individually and their combined (net) effect on attached canopies.

The steps required for the determination of wind loads on attached canopies are shown in Table 30.9-1.

EXCEPTIONS:

1. As an alternative to using the (GC_p) value from Figure 30.9-2A for buildings with a mean roof height between 60 ft (18.3 m) and 90 ft (27.4 m), the value of GC_p may be linearly interpolated between the value for a mean roof height of 60 ft (18.3 m) from Figure 30.9-1A and the value for a mean roof height of 90 ft (27.4 m) from Figure 30.9-2A for each specific h_c/h_e of the attached canopy.
2. As an alternative to using the (GC_{pn}) value from Figure 30.9-2B for buildings with a mean roof height between 60 ft (18.3 m) and 90 ft (27.4 m), the value of GC_{pn} may be linearly interpolated between the value for a mean roof height of 60 ft (18.3 m) from Figure 30.9-1B and the value for a mean roof height of 90 ft (27.4 m) from Figure 30.9-2B for each specific h_c/h_e of the attached canopy.

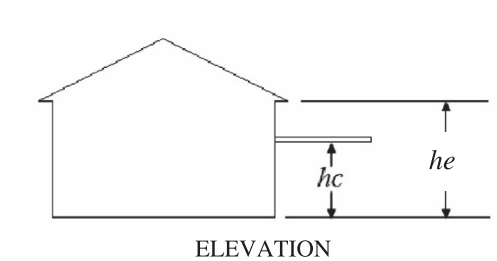


Table 30.9-1. Steps to Determine C&C Wind Loads on Attached Canopies.

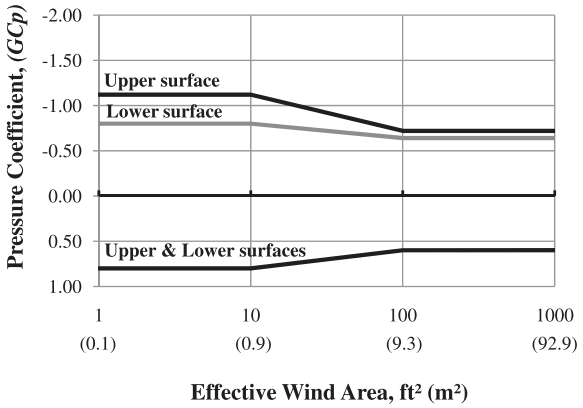
Step 1: Determine risk category of building; see Table 1.5-1.
Step 2: Determine the basic wind speed, V, for applicable risk category; see Figure 26.5-1.
Step 3: Determine wind load parameters:
- Wind directionality factor, K_d; see Section 26.6 and Table 26.6-1.
- Exposure category B, C, or D; see Section 26.7.
- Topographic factor, K_{zt}; see Section 26.8 and Figure 26.8-1.
- Ground elevation factor, K_e; see Section 26.9 and Table 26.9-1.



Step 4: Determine velocity pressure exposure coefficient, K_h; see Table 26.10-1.
Step 5: Determine velocity pressure, q_h, at mean roof height h using Equation (26.10-1).
Step 6: Determine surface or net pressure coefficient (GC_p) or (GC_{pn}) using Figure 30.9-1A-B [buildings with $h \le 60$ ft ($h \le 18.3$ m)] or Figure 30.9-2A-B [buildings with $h > 60$ ft ($h > 18.3$ m)].
Step 7: Calculate wind pressure, p, using Equation (30.9-1).

@seismicisolation

Diagram

Pressure Coefficient

Notation

hc = Mean canopy height, ft (m).
he = Mean eave height, ft (m).
(GCp) = Pressure coefficients.
q_h = Velocity pressure evaluated at height $z = h$, lb/ft2 (N/m2).

Notes

1. Pressures are based on the most critical values for all ratios of hc/he.
2. Vertical scale denotes (GCp) to be used with q_h.
3. Horizontal scale denotes effective wind area, ft^2 (m^2).
4. Negative signs signify pressures acting away from the surface.

Figure 30.9-1A. Pressure coefficients on separate surfaces of attached canopies on buildings with $h \leq 60$ ft ($h \leq 18.3$ m).

PART 5: NONBUILDING STRUCTURES

30.10 CIRCULAR BINS, SILOS, AND TANKS WITH $h \leq 120$ft ($h \leq 36.6m$)

Wind pressures on surfaces of isolated circular bins, silos, and tanks shall be calculated from Sections 30.10.1 through 30.10.5.

Grouped circular bins, silos, and tanks of similar size with center-to-center spacing greater than 2 diameters shall be treated as isolated structures. For spacings less than 1.25 diameters, the structures shall be treated as grouped and the wind pressure shall be determined from Section 30.10.6. For intermediate spacings, linear interpolation of the C_p (or C_f) values shall be used.

The steps required for the determination of wind loads for circular bins, silos, and tanks are shown in Table 30.10-1.

30.10.1 Design Wind Pressure Design wind pressure on C&C for isolated circular bins, silos, and tanks in $(lb/ft^2)(N/m^2)$ shall be determined from the following equation:

$$p = q_h K_d [(GC_p) - (GC_{pi})] \qquad (30.10\text{-}1)$$

where

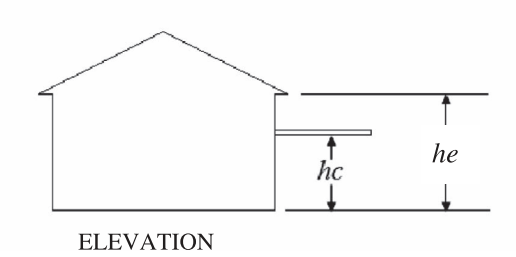
q_h = Velocity pressure for all surfaces evaluated at mean roof height h
K_d = Wind directionality factor; see Section 26.6.
(GC_p) = External pressure coefficients given in

- Section 30.10.2 for walls
- Section 30.10.5 for underneath sides
- Section 30.10.4 for roofs

(GC_{pi}) = Internal pressure coefficient given in Table 26.13-1 and Section 30.11.3.

30.10.2 External Walls of Isolated Circular Bins, Silos, and Tanks The external pressures on the walls of circular bins, silos, and tanks shall be determined from the external pressure

Table 30.10-1. Steps to Determine C&C Wind Loads for Circular Bins, Silos, and Tanks.



Step 1: Determine risk category; see Table 1.5-1.
Step 2: Determine the basic wind speed, V, for applicable risk category; see Figure. 26.5-1.
Step 3: Determine wind load parameters:
- Wind directionality factor, K_d; see Section 26.6 and Table 26.6-1.
- Exposure Category B, C, or D; see Section 26.7.
- Topographic factor, K_{zt}; see Section 26.8 and Figure 26.8-1.
- Ground elevation factor, K_e; see Section 26.9 and Table 26.9-1.
- Enclosure classification; see Section 26.12.
- Internal pressure coefficient (GC_{pi}); see Section 26.13 and Section 30.11.3.

Step 4: Determine velocity pressure exposure coefficient, K_z or K_h; see Table 26.10-1.
Step 5: Determine velocity pressure, q_h, Equation (26.10-1).
Step 6: Determine external pressure coefficient (GC_p).
- Walls; see Sections 30.10.2 and 30.10.6.
- Roofs; see Sections 30.10.4 and 30.10.6.

Step 7: Calculate wind pressure, p, using Equation (30.10-1).

@seismicisolation

coefficients (GC_p) as a function of the angle α, given as follows for the shape ranges indicated:

$$GC_{p(\alpha)} = k_b C_{(\alpha)} \quad (30.10\text{-}2)$$

where the cylinder (diameter D) is standing on the ground or supported by columns giving a clearance height (C) less than the height of the cylinder (H), as shown in Figure 30.10-1.

H/D is in the range 0.25 to 4.0 inclusive. α = angle from the wind direction to a point on the wall of a circular bin, silo, or tank, in degrees.

$$k_b = 1.0 \text{ for } C_{(\alpha)} \geq -0.15, \text{ or}$$
$$= 1.0 - 0.55(C(\alpha) + 0.15)\log_{10}(H/D) \quad (30.10\text{-}3)$$
$$\text{for } C_{(\alpha)} < -0.15$$

$$C_{(\alpha)} = -0.5 + 0.4\cos\alpha + 0.8\cos 2\alpha + 0.3\cos 3\alpha$$
$$1 - 0.1\cos 4\alpha - 0.05\cos 5\alpha \quad (30.10\text{-}4)$$

Figure 30.10-1 lists the external pressure coefficients for walls, which include the graphic distribution of the external pressure, $GC_{p(\alpha)}$, around the perimeter of the wall.

30.10.3 Internal Surface of Exterior Walls of Isolated Open-Topped Circular Bins, Silos, and Tanks The pressures on the internal surface of exterior walls of open-topped circular bins, silos, and tanks shall be determined from Equation (30.10-5):

$$GC_{pi} = -0.9\text{–}0.35\ \log_{10}(H/D) \quad (30.10\text{-}5)$$

30.10.4 Roofs of Isolated Circular Bins, Silos, and Tanks The external pressures on the roofs or lids of bins, silos, or tanks of circular cross section shall be equal to the external pressure coefficients, (GC_p), given in Figure 30.10-2 for Zones 1, 2, 3, and 4.

Zone 3 is applicable to the windward edges of roofs with slope less than or equal to 30 degrees, and Zone 4 is applicable to the region near the cone apex for roofs with slope greater than 15 degrees. The applicable areas are shown in Figure 30.10-2.

30.10.5 Undersides of Isolated Elevated Circular Bins, Silos, and Tanks (GC_p) values for the undersides of elevated circular bins, silos, and tanks shall be taken as 1.2 and −0.9 for Zone 3 and 0.8 and –0.6 for Zone 1 and Zone 2, as shown in Figure 30.10-2.

30.10.6 Roofs and Walls of Grouped Circular Bins, Silos, and Tanks Closely spaced groups with center-to-center spacing less than 1.25D, the external pressures of grouped bins, silos, or tanks, shall be equal to the external pressure coefficients, (GC_p), given in Figure 30.10-3 for Zones 1, 2, 3a, 3b, and 4 for roofs and Figure 30.10-4 for Zones 5a, 5b, 8, and 9 for walls.

30.11 ROOFTOP SOLAR PANELS FOR BUILDINGS OF ALL HEIGHTS WITH FLAT ROOFS OR GABLE OR HIP ROOFS WITH SLOPES LESS THAN 7 DEGREES

The design wind pressures for rooftop solar modules and panels shall be determined in accordance with Section 29.4.3 for rooftop solar arrays that conform to the geometric requirements specified in Section 29.4.3.

30.12 ROOF PAVERS FOR BUILDINGS OF ALL HEIGHTS WITH ROOF SLOPES LESS THAN OR EQUAL TO 7 DEGREES

The design net uplift pressures for roof pavers, for buildings of all heights with roof slopes less than or equal to 7 degrees, shall be determined from the following equations:

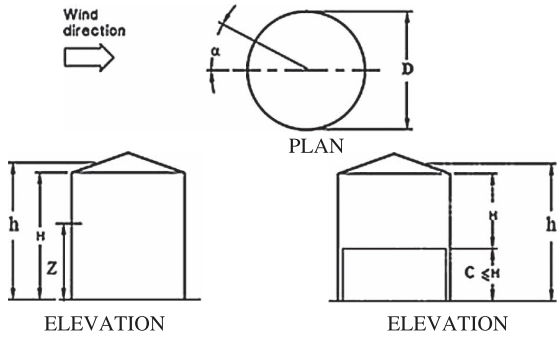
$$p = q_h K_d C_{L_{net}} (\text{lb/ft}^2) \quad (30.12\text{-}1)$$

where

K_d = Wind directionality factor, see Section 26.6

q_h = Velocity pressure evaluated at mean height h, as defined in Section 26.10, of the roof on which the pavers are located;

$C_{L_{net}}$ = Design net uplift pressure coefficient which shall be taken as



(a) The value of external pressure coefficient, GC_p, from Figures 30.3-2A and 30.5-1,
or
(b) Determined by approved wind tunnel tests performed in accordance with Chapter 31,
or
(c) Determined by methods described in the recognized literature.

30.13 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

No consensus standards and other documents that shall be considered part of this standard are referenced in this chapter.

@seismicisolation

CHAPTER 31
WIND TUNNEL PROCEDURE

31.1 SCOPE

The Wind Tunnel Procedure shall be used where required by Sections 27.1.3, 28.1.3, 29.1.3, and 30.1.3. The Wind Tunnel Procedure shall be permitted for any building or other structure in lieu of the design procedures specified in Chapter 27 [main wind force resisting system (MWFRS) for buildings of all heights], Chapter 28 (MWFRS of low-rise buildings), Chapter 29 (MWFRS of all other structures), and Chapter 30 (components and cladding [C&C] for all building types and other structures).

The results of numerical Wind Tunnel Procedures (i.e., the use of computational fluid dynamics for wind engineering purposes) shall be verified, validated by a physical wind tunnel procedure in accordance with ASCE 49, and subject to an independent peer review, in accordance with ASCE 7 Section 1.3.1.3.4.

User Note: Chapter 31 may always be used for determining wind pressures for the MWFRS and/or for C&C of any building or other structure. This method is considered to produce the most accurate wind pressures and loads of any method specified in this standard.

31.2 TEST CONDITIONS

Wind tunnel tests, or similar tests using fluids other than air, used for the determination of design wind loads for any building, other structure, portion of structure, or component, shall be conducted in accordance with this section. Tests for the determination of the mean, fluctuating, and peak forces and pressures shall meet the requirements of ASCE 49.

31.3 DYNAMIC RESPONSE

Tests for the purpose of determining the dynamic response of a building, other structure, portion of structure, or component shall be in accordance with Section 31.2. The tested model and associated analysis shall account for mass distribution, stiffness, and damping.

31.4 SITE SPECIFIC LOAD EFFECTS FOR BUILDINGS, OTHER STRUCTURES, AND COMPONENTS

Load effects for buildings, other structures, and components at a single, specific site shall be permitted to be determined in accordance with this section. Wind tunnel tests shall conform with the requirements of Sections 31.2 and 31.3.

31.4.1 Mean Recurrence Intervals of Load Effects The load effect required for strength design shall be determined for the same mean recurrence interval as for the analytical method by using a rational analysis method, as defined in the recognized literature, for combining the directional wind tunnel data with the directional meteorological data or probabilistic models based thereon. The load effect required for allowable stress design shall be equal to the load effect required for strength design divided by 1.6. For buildings or other structures that are sensitive to possible variations in the values of the dynamic parameters, sensitivity studies shall be required to provide a rational basis for design recommendations.

31.4.2 Limitations on Wind Speeds The wind speeds, and probabilistic estimates based thereon, shall be subject to the limitations described in Section 26.5.3.

31.4.3 Wind Directionality The directional wind climate based on recorded or simulated directional wind speed data shall be considered in determining wind loads, and the data shall be presented as part of the wind tunnel report submitted to the Authority Having Jurisdiction. The method for combining wind tunnel model data with information on wind speed and direction at the project site shall also be clearly stated in the Wind Tunnel Report. Variation in the wind direction, based upon uncertainty in the wind climate data, shall be considered when determining the wind loading, and the design wind loads shall be based on the largest values that result from this uncertainty. Consideration of uncertainty in the wind direction is not required in the determination of serviceability-related wind effects.

31.4.4 Limitations on Loads Loads for the MWFRS, determined by wind tunnel testing, shall be limited such that the overall principal loads in the x and y directions are not less than 80% of those that would be obtained from Chapter 27 or Chapter 28 for buildings, or Chapter 29 for appurtenances or other structures. The overall principal load for buildings shall be based on the overturning moment for flexible buildings and the base shear for other buildings. The overall principal load for other structures shall be based on the overturning moment for flexible structures and the base shear for other structures.

Pressures for C&C, determined by wind tunnel testing, shall be limited to not less than 80% of those calculated for Zone 4 for walls and Zone 1 for roofs, using the procedure in Chapter 30. These zones refer to those shown in Figures. 30.3-1, 30.3-2A–C, 30.3-3, 30.3-4, 30.3-5A–B, 30.3-6, 30.3-7, and 30.5-1.

The limiting values of 80% may be reduced to 50% for the MWFRS and 65% for C&C if either of the following conditions applies:

1. There were no specific influential buildings or objects within the detailed proximity model.
2. Loads and pressures from supplemental tests for all significant wind directions in which specific influential buildings or objects are replaced by the roughness representative of

@seismicisolation

the adjacent roughness condition, but not rougher than Exposure B, are included in the test results.

31.4.5 Limitations on Wind Loads for Ground-Mounted Fixed-Tilt Solar Panel Systems For ground-mounted fixed-tilt solar panel systems that meet the limitations and geometry requirements of Section 29.4.5.1, the minimum design wind load based on a wind tunnel study shall not be less than 65% for components and cladding (C&C) and 50% for the main wind force resisting system (MWFRS) of the values resulting from Section 29.4.5, subject to the conditions of Section 31.4.3. Wind load values lower than these limits shall be permitted when an independent peer review of the wind tunnel test is performed, in accordance with Section 31.6. The minimum design wind force based on a wind tunnel study for ground-mounted fixed-tilt solar panel systems need not comply with the minimum net pressure of 16 lb/ft^2 (0.77 kN/m^2) per Section 30.2.2.

31.5 LOAD EFFECTS FOR BUILDINGS, OTHER STRUCTURES, AND COMPONENTS USED AT MULTIPLE SITES

31.5.1 Wind Loads Wind loads on buildings, other structures, portions of structures, or components used at multiple sites, shall be permitted to be determined by wind tunnel tests by determining load coefficients for use in the analysis equations of the Directional Procedure in Chapters 27 and 29 for MWFRS and in Part 4 of Chapter 30 for C&C. Alternatively, the loads are permitted to be specified with an analysis method defined in the wind tunnel test report. It is not required to include specific nearby buildings in the testing when results are to be used for multiple sites.

The wind tunnel tests shall conform with the requirements of Sections 31.2 and 31.3.

Data analysis shall consider wind loads from all wind directions. Generic load coefficients shall be calculated to be consistent with coefficients in Chapters 27, 29, and 30, or shall be defined to apply to an analysis procedure specified in the test report.

The test report shall include data collection methods, data analysis, wind field modeling, wind tunnel model details, measured wind loads, conversion of data into generic coefficients, and conditions of applicability of results. Wind tunnel results shall not be extrapolated to geometric configurations that were not anticipated by the wind tunnel study. Interpolation between two or more tests shall be permitted. The limitations of the wind tunnel study shall be clearly reported.

31.5.2 Limitations on Wind Loads for Rooftop Solar Panels For photovoltaic solar panel systems that meet the limitations and geometry requirements of Figure 29.4-7, the minimum design wind load based on a wind tunnel study shall not be less than 65% of the values resulting from 29.4-7, subject to the conditions of Section 31.4.3. The minimum design wind force based on a wind tunnel study for roof-mounted solar panel systems need not comply with the minimum net pressure of 16 lb/ft^2 (0.77 kN/m^2) as per ASCE 7, Section 30.2.2.

31.5.3 Peer Review Requirements for Wind Tunnel Tests of Buildings, Other Structures, and Components used at Multiple Sites For wind loads on buildings, other structures, and components used at multiple sites determined by wind tunnel tests, an independent peer review of the wind tunnel test shall be performed in accordance with Section 31.6. For photovoltaic solar panel systems that meet the limitations and geometrical requirements of Figure 29.4-7, wind load values lower than those indicated in Section 31.5.2 shall be permitted when an independent peer review of the wind tunnel test is performed, in accordance with Section 31.6.

31.6 PEER REVIEW REQUIREMENT FOR WIND TUNNEL TESTS

When an independent peer review is required by Section 31.5.3 or 31.4.5, it shall be an objective, technical review performed by knowledgeable reviewer(s) experienced in performing wind tunnel studies on buildings and similar systems, and in properly simulated atmospheric boundary layers or wind fields. The minimum qualifications for the peer reviewer shall include the following:

- Peer reviewer shall be independent from the wind tunnel laboratory that performed the tests and report and shall bear no conflict of interest.
- Peer reviewer shall have technical expertise in the application of wind tunnel studies on buildings, other structures, or components, similar to that being reviewed.
- Peer reviewer shall have experience in performing or evaluating boundary layer wind tunnel studies and shall be familiar with the technical issues and regulations governing the Wind Tunnel Procedure in ASCE 49, as it is applied to the building, other structure, or component under consideration.

The peer reviewer shall review the wind tunnel report, including, but not limited to, data collection methods, data analysis, wind field modeling, building, other structure, or component wind tunnel model, resulting wind loads, conversion of data into design values, conditions of applicability of results, and other relevant issues identified by the reviewer.

The peer reviewer shall submit a written report to the Authority Having Jurisdiction and the client. The report shall include, at a minimum, statements regarding the following: scope of peer review with limitations defined; the status of the wind tunnel study at time of review; conformance of the wind tunnel study with the requirements of ASCE 49 and Section 31.5.1; conclusions of the reviewer identifying areas that need further review, investigation, and/or clarification; recommendations; and whether, in the reviewer's opinion, the wind loads derived from the wind tunnel study are in conformance with ASCE 7 for the intended use(s).

31.7 WIND-BORNE DEBRIS

Glazing in buildings in wind-borne debris regions shall be in accordance with Section 26.12.3.

31.8 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

This section lists the consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

ASCE 49, *Wind Tunnel Testing for Buildings and Other Structures*, American Society of Civil Engineers, 2020.

@seismicisolation

CHAPTER 32
TORNADO LOADS

32.1 PROCEDURES

32.1.1 Scope Buildings and other structures classified as Risk Category III or IV and located in the tornado-prone region as shown in Figure 32.1-1, including the main wind force resisting system (MWFRS) and all components and cladding (C&C) thereof, shall be designed and constructed to resist the greater of the tornado loads determined in accordance with the provisions of this chapter or the wind loads determined in accordance with Chapters 26 through 31, using the load combinations provided in Chapter 2.

User Note: The tornado loads specified in this chapter provide reasonable consistency with the reliability delivered by the existing criteria in Chapters 26 and 27 for MWFRS, and therefore are only required for Risk Category III and IV buildings and other structures (see Return Period discussion in Section C32.5.1 for more information). The tornado loads are based on tornado speeds using 1,700- and 3,000-year return periods for Risk Category III and IV, respectively (which are the same return periods used for basic wind speeds in Chapter 26). The tornado speed at any given geographic location will range from approximately Enhanced Fujita Scale EF0 – EF2 intensity, depending on the risk category and effective plan area of the building or other structure (see Section C32.5.1). Options for protection of life and property from more intense tornadoes include construction of a storm shelter and/or design for longer-return-period tornado speeds as provided in Appendix G, including performance-based design. A building or other structure designed for tornado loads determined exclusively in accordance with Chapter 32 cannot be designated as a storm shelter without meeting additional critical requirements provided in the applicable building code and ICC 500, the ICC/NSSA *Standard for the Design and Construction of Storm Shelters*. See Commentary Section C32.1.1 for an in-depth discussion on storm shelters.

32.1.2 Permitted Procedures The design tornado loads for buildings and other structures, including the MWFRS and C&C elements thereof, shall be determined using one of the procedures as specified in this section and subject to the applicable limitations of Chapters 26 through 32, excluding Chapter 28.

An outline of the overall process for the determination of the tornado loads, including section references, is provided in Figure 32.1-3.

32.1.2.1 Tornado Loads on the Main Wind Force Resisting System Tornado loads for the MWFRS shall be determined using one or more of the following procedures, as modified by Chapter 32:

1. Directional Procedure for buildings of all heights as specified in Chapter 27 for buildings meeting the requirements specified therein;
2. Directional Procedure for Building Appurtenances (such as rooftop structures and rooftop equipment) and Other Structures (such as solid freestanding walls and solid freestanding signs, chimneys, tanks, open signs, single-plane open frames, and trussed towers) as specified in Chapter 29 for buildings meeting the requirements specified therein; or
3. Wind Tunnel Procedure for all buildings and all other structures as specified in Chapter 31 for buildings meeting the requirements specified therein.

32.1.2.2 Tornado Loads on Components and Cladding Tornado loads on the C&C of all buildings and other structures shall be determined using one or more of the following procedures, as modified by Chapter 32:

1. Analytical Procedures as specified in Parts 1 through 5, as appropriate, of Chapter 30, for buildings or other structures meeting the requirements specified therein; or
2. Wind Tunnel Procedure for all buildings and other structures as specified in Chapter 31, for buildings meeting the requirements specified therein.

32.1.3 Performance-Based Procedures Tornado design of buildings and other structures using performance-based procedures shall be permitted subject to the approval of the Authority Having Jurisdiction. The performance-based tornado design procedures used shall, at a minimum, conform to Section 1.3.1.3 and be documented and submitted to the Authority Having Jurisdiction in accordance with Section 1.3.1.3.

32.2 DEFINITIONS

The following definitions apply to the provisions of Chapter 32. Terms not defined in this chapter shall be defined in accordance with Chapters 26 through 31, as appropriate, excluding Chapter 28.

ASCE TORNADO DESIGN GEODATABASE: The ASCE database (version 2022-1.0) of geocoded tornado speed design data.

OTHER STRUCTURES, SEALED: A structure that is completely sealed or has controlled ventilation such that tornado-induced atmospheric pressure changes will not be transmitted to the inside of the structure, including but not limited to certain tanks and vessels.

TORNADO-PRONE REGION: The area of the conterminous United States most vulnerable to tornadoes, as shown in Figure 32.1-1.

@seismicisolation

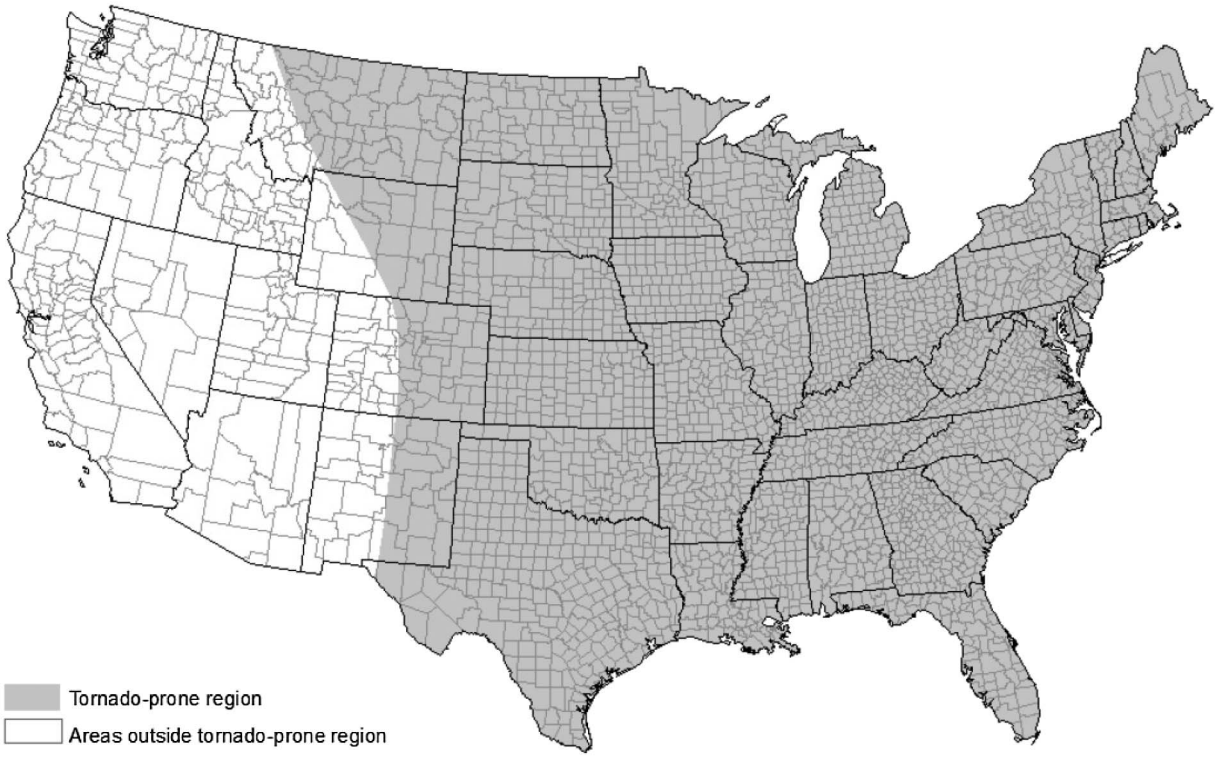

Figure 32.1-1. Tornado-prone region.

32.3 SYMBOLS AND NOTATION

The following symbols apply only to the provisions of Chapter 32. Symbols and notations not defined in this chapter shall be defined in accordance with Chapters 26 through 31, as appropriate, excluding Chapter 28.

A_e = Effective plan area of the building, other structure, or facility, ft^2 (m^2), as defined in Section 32.5.4
F_{hT} = Lateral design tornado force for rooftop structures and equipment from Equation (32.16-3), lb (N)
F_T = Design tornado force for certain other structures from Equation (32.16-2), lb (N)
F_{vT} = Vertical design tornado force for rooftop structures and equipment from Equation (32.16-4), lb (N)
G_T = Tornado gust-effect factor as defined in Section 32.11
(GC_{piT}) = Product of internal pressure coefficient that includes the effects of atmospheric pressure change and gust-effect factor, to be used in determination of tornado loads for buildings and some other structures, as determined in Section 32.13
K_{dT} = Tornado directionality factor as defined in Section 32.6
K_{hTor} = Tornado velocity pressure exposure coefficient evaluated at height $z = h$, as determined in Section 32.10
K_{vT} = Tornado pressure coefficient adjustment factor for vertical winds as defined in Section 32.14
K_{zTor} = Tornado velocity pressure exposure coefficient evaluated at height z, as determined in Section 32.10
p_{pT} = Combined net tornado design pressure on a parapet from Equation (32.15-3), lb/ft^2 (N/m^2)
p_T = Design tornado pressure to be used in determination of tornado loads for buildings and for certain other structures, lb/ft^2 (N/m^2)
q_{hT} = Tornado velocity pressure evaluated at height $z = h$, lb/ft^2 (N/m^2)
q_{pT} = Tornado velocity pressure evaluated at top of parapet from Equations (32.15-3) and (32.17-4), lb/ft^2 (N/m^2)
q_{zop} = Tornado velocity pressure internal pressure determination for partially enclosed buildings, lb/ft^2 (N/m^2)
q_{zT} = Tornado velocity pressure evaluated at height z above ground, lb/ft^2 (N/m^2)
V_T = Tornado speed obtained from Figures 32.5-1 and 32.5-2, mi/h (m/s). The tornado speed corresponds to a 3 s gust speed at 33 ft (10 m) above the ground.
z_{op} = Level of the lowest opening in the building that could affect the positive internal pressure, lb/ft^2 (N/m^2)

32.4 GENERAL

32.4.1 Sign Convention The combined effects of internal pressures and atmospheric pressure change, expressed in coefficient form by $(\boldsymbol{GC}_{piT})$, shall follow the same sign convention as provided in Section 26.4, where positive pressure acts toward the surface and negative pressure acts away from the surface.

32.4.2 Critical Load Condition Values of external pressures shall be combined algebraically with the combined effects of internal pressures and atmospheric pressure change to determine the most critical load.

32.5 TORNADO HAZARD MAPS

32.5.1 Tornado Speed The tornado speed, V_T, used in the determination of tornado loads on buildings and other structures shall be determined from Figures 32.5-1 and 32.5-2 as follows:

1. For Risk Category III buildings and structures, use Figures 32.5-1A through 32.5-1H.

@seismicisolation

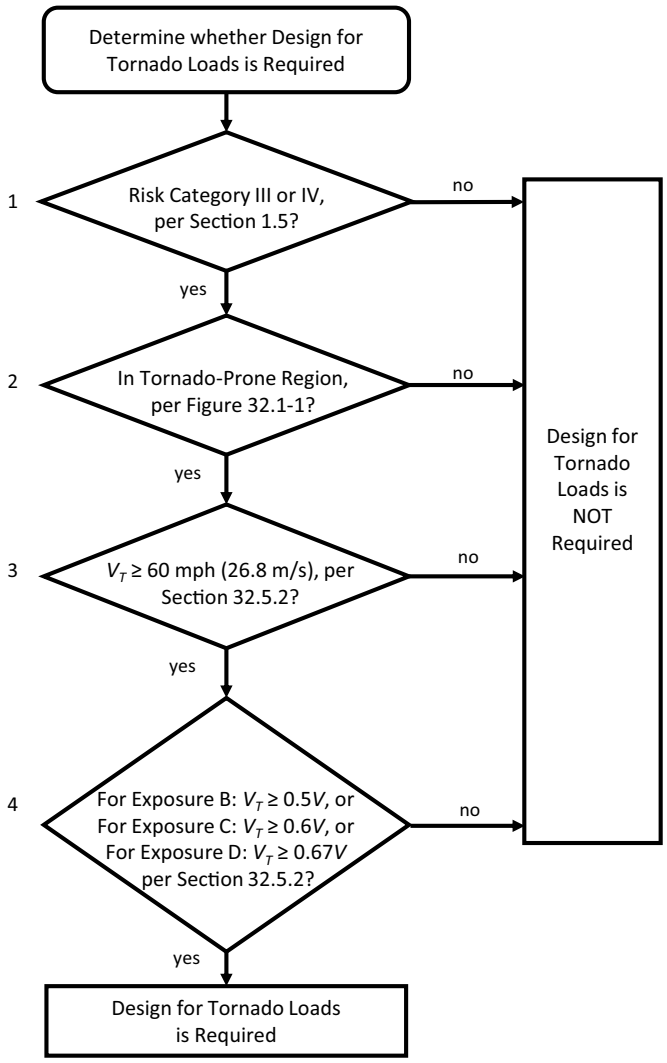

Figure 32.1-2. Flowchart of process for determining when design for tornado loads is required.

@seismicisolation

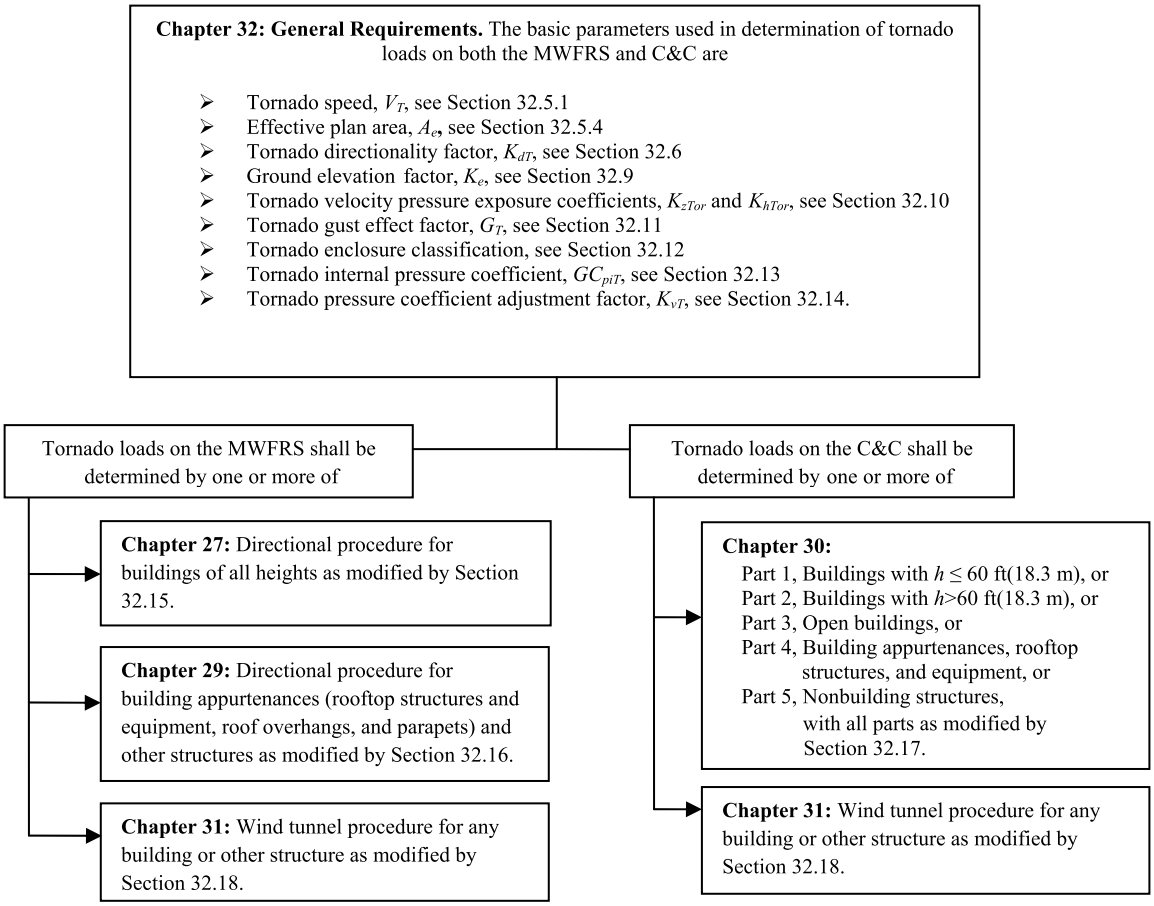

Figure 32.1-3. Outline of process for determining tornado loads.

2. For Risk Category IV buildings and structures, use Figures 32.5-2A through 32.5-2H.

To select the appropriate tornado hazard map to use for the assigned risk category, the effective plan area, A_e, of the building, other structure, or facility, shall be determined in accordance with Section 32.5.4 and shall be rounded up to next available mapped A_e, including 1; 2,000; 10,000; 40,000; 100,000; 250,000; 1,000,000; and 4,000,000 ft^2 (0.1; 186; 929; 3,716; 9,290; 23,226; 92,903; and 371,612 m^2). Alternatively, linear interpolation of tornado speed between maps using the logarithm of the effective plan area size is permitted.

Alternatively, it shall be permitted to use the tornado speeds from the ASCE Tornado Design Geodatabase. The ASCE Tornado Design Geodatabase is available at the ASCE 7 Hazard Tool (https://asce7hazardtool.online) or approved equivalent.

32.5.2 Design for Tornado Loads Not Required For Risk Category III and IV buildings and other structures determined to have tornado speeds V_T < 60 mi/h (26.8 m/s), design for tornado loads shall not be required. Where $V_T \ge 60$ mi/h (26.8 m/s) but is less than the following threshold speeds then design for tornado loads shall not be required:

1. For Exposure B: $V_T < 0.5V$, or
2. For Exposure C: $V_T < 0.6V$, or
3. For Exposure D: $V_T < 0.67V$,

where V is the basic wind speed determined in accordance with Section 26.5 and the exposure category is determined in accordance with Section 26.7.3, based on the exposure resulting in the greatest wind loads for any wind direction at the site.

32.5.3 Direction of Tornadic Wind The tornadic wind shall be assumed to come from any horizontal direction.

32.5.4 Effective Plan Area The effective plan area, A_e, of the building or other structure shall be determined in accordance with this section.

32.5.4.1 Essential Facilities For Essential Facilities and buildings and other structures required to maintain the functionality of Essential Facilities, the effective plan area shall be equal to the area of the smallest convex polygon enclosing both the Essential Facility and all of the buildings and other structures that maintain the functionality of the Essential Facility.

32.5.4.2 Other than Essential Facilities For buildings and structures that are not designated as Essential Facilities and are not required to maintain the functionality of Essential Facilities, the effective plan area shall be equal to the area of the smallest convex polygon enclosing the plan of the building, other structure, or facility. It is permitted to reduce the effective plan area to that of the effective plan area of the largest structurally independent building or other structure, which does not share structural components with adjacent buildings or other structures.

32.5.4.3 Ground-Mounted Photovoltaic Panel Systems The effective plan area, A_e, of ground-mounted photovoltaic

@seismicisolation

panel systems shall be equal to the effective plan area of the largest structurally independent photovoltaic support structure that does not share structural components with other adjacent structures.

32.6 TORNADO DIRECTIONALITY FACTOR

The tornado directionality factor, K_{dT}, shall be determined from Table 32.6-1 and shall be used to determine the tornado loads in accordance with Sections 32.15 through 32.17.

32.7 TORNADO EXPOSURE

Tornado velocity pressure exposure coefficients K_{zTor} and K_{hTor} are determined in Section 32.10.1. Exposure requirements in Section 26.7 shall not apply to the determination of K_{zTor} and K_{hTor}.

32.8 TOPOGRAPHIC FACTOR

Tornado velocity pressures q_{zT} and q_{hT} are determined in Section 32.10.2. Topographic speedup effects in Section 26.8 shall not apply to the determination of q_{zT} and q_{hT}.

32.9 GROUND ELEVATION FACTOR

The ground elevation factor to adjust for air density, K_e, shall be determined in accordance with Section 26.9 and shall be used to determine the tornado velocity pressure in accordance with Section 32.10.2.

32.10 TORNADO VELOCITY PRESSURE

32.10.1 Tornado Velocity Pressure Exposure Coefficient A tornado velocity pressure exposure coefficient, K_{zTor} or K_{hTor}, as applicable, shall be determined from Table 32.10-1.

32.10.2 Tornado Velocity Pressure Tornado velocity pressure, q_{zT}, evaluated at height z above ground, shall be determined in accordance with the following equation:

$$q_{zT} = 0.00256 K_{zTor} K_e V_T^2 \ (\text{lb/ft}^2); V_T \text{ in mi/h} \qquad (32.10\text{-}1)$$

$$q_{zT} = 0.613 K_{zTor} K_e V_T^2 \ (\text{N/m}^2); V_T \text{ in m/s} \qquad (32.10\text{-}1.\text{SI})$$

where

K_{zTor} = Tornado velocity pressure exposure coefficient, see Section 32.10.1;
K_e = Ground elevation factor, see Section 32.9;
V_T = Tornado speed, see Section 32.5; and
q_{zT} = Tornado velocity pressure at height z.

The velocity pressure at mean roof height shall be computed as $q_{hT} = q_{zT}$ evaluated from Equation (32.10-1) using K_{zTor} at mean roof height h.

32.11 TORNADO GUST EFFECTS

32.11.1 Tornado Gust-Effect Factor The tornado gust-effect factor, G_T, for a building or other structure shall be 0.85 or calculated from Equation (26.11-6) using Exposure C terrain exposure constants.

32.11.2 Limitations Where the combined gust-effect factors and pressure coefficients (GC_p), (GC_{piT}), and (GC_{pf}) are given in figures and tables, the gust-effect factor shall not be determined separately.

32.12 TORNADO ENCLOSURE CLASSIFICATION

32.12.1 General For the purpose of determining internal pressure coefficients for tornadoes, buildings and other structures for which tornado internal pressure coefficients, (GC_{piT}), apply shall have an enclosure classification assigned in accordance with this section. If a building or other structure satisfies both the "open" and "partially enclosed" tornado enclosure classification definitions, it shall be classified as a "partially open" building or other structure.

32.12.2 Openings To assign the tornado enclosure classification, the amount of openings in the building envelope shall be determined by taking each wall of the building or other structure, assuming it functions as the windward wall, and summing the total area of openings present with respect to the area of the remaining building envelope. Buildings shall be classified as enclosed, partially enclosed, partially open, or open as defined in Section 26.2. Other structures shall be classified as sealed, as defined in Section 32.2, or enclosed, partially enclosed, partially open, or open as defined in Section 26.2.

Where not required by Section 32.12.3 to protect glazed openings, enclosed buildings and other structures shall either (1) be reevaluated for classification as partially enclosed, with all unprotected glazed openings on each assumed windward wall considered as openings; or (2) be protected in accordance with Section 32.12.3.1.

32.12.3 Protection of Glazed Openings Glazed openings shall be protected as specified in this section for Essential Facilities and for buildings and other structures required to maintain the functionality of Essential Facilities.

32.12.3.1 Protection Requirements for Glazed Openings Glazing in buildings requiring protection shall be protected with an impact-protective system or shall be impact-resistant glazing. Impact-protective systems shall be either (a) permanently affixed non-operable systems or (b) permanently affixed operable systems capable of being fully deployed from inside the building within five minutes and used in buildings that are staffed 24 hours per day.

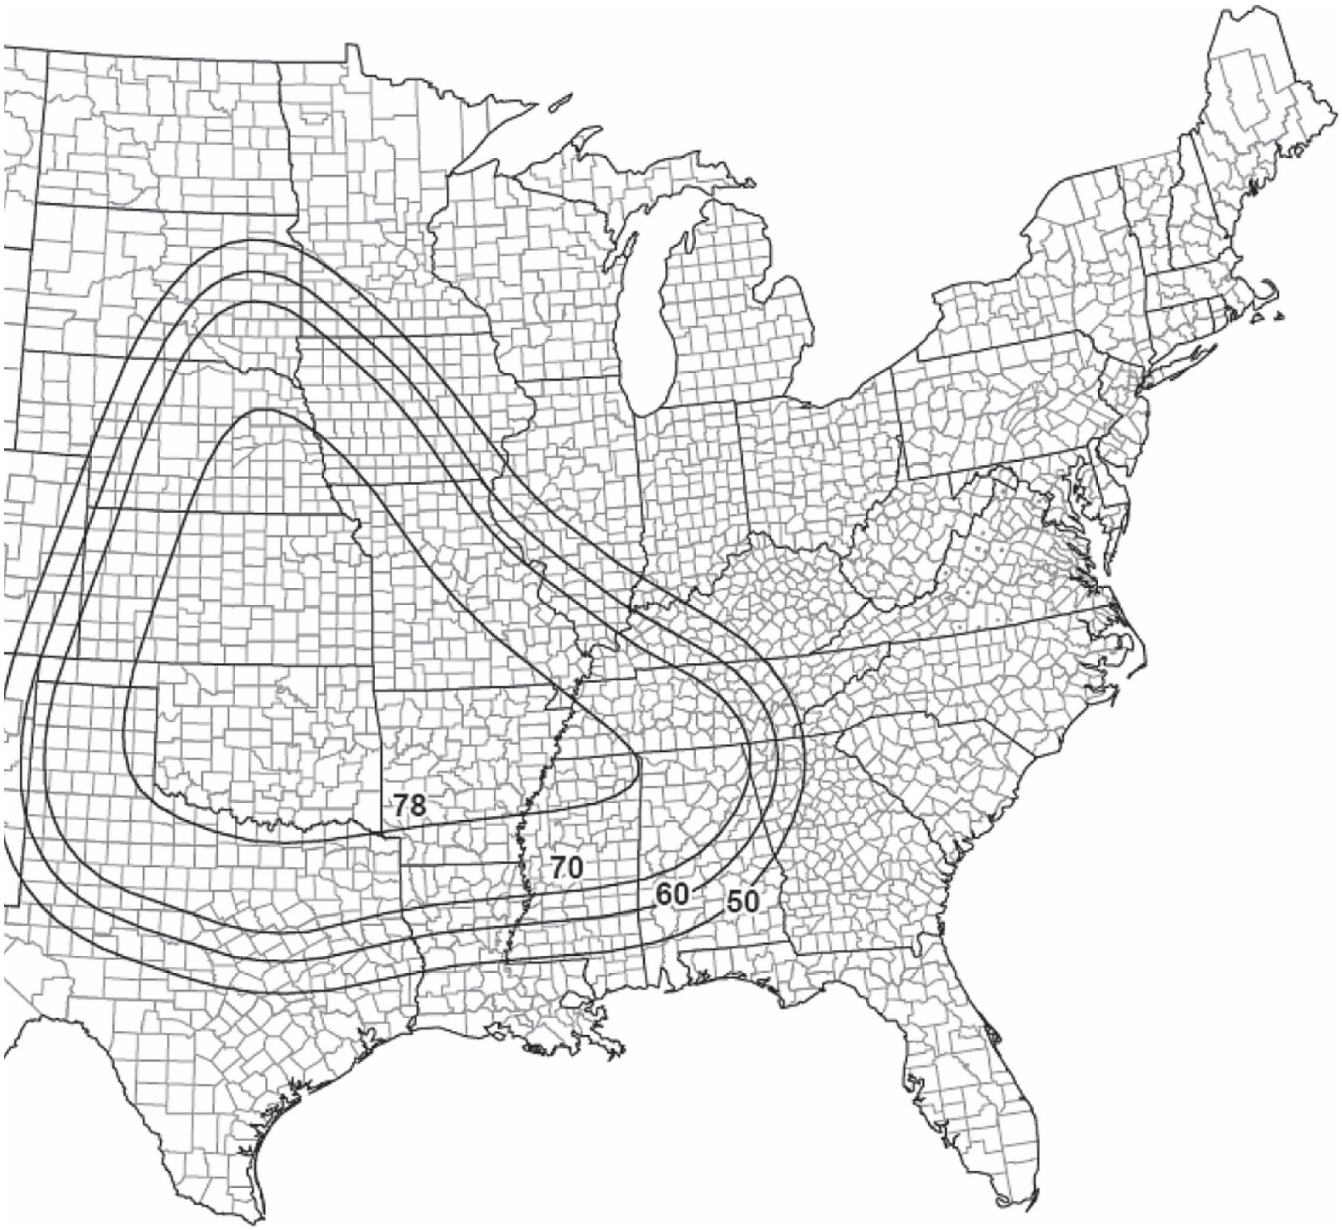
Impact-protective systems and impact-resistant glazing shall be subjected to missile tests in accordance with ASTM E1996 using missile level D or E as described in Table 2 of ASTM E1996. Testing to demonstrate compliance with ASTM E1996 shall be in accordance with ASTM E1886. Impact-resistant glazing and impact-protective systems shall comply with the pass/fail criteria of Section 7 of ASTM E1996. Glazing in sectional doors, rolling doors, and flexible doors shall be subjected to missile tests in accordance with ANSI/DASMA 115 as applicable. Glazing and impact-protective systems shall comply with the "Enhanced Protection" requirements of Table 3 of ASTM E1996, with tornado speed used in place of basic wind speed for determination of wind zone.

EXCEPTION: Other testing methods and/or performance criteria are permitted to be used where approved.

32.13 TORNADO INTERNAL PRESSURE COEFFICIENTS

Tornado internal pressure coefficients, (GC_{piT}), shall be determined from Table 32.13-1 based on building and other structure enclosure classifications determined in accordance with Section 32.12.1.

@seismicisolation



Notes:

1. Values are 3 s gust speeds in mi/h at 33 ft (10 m) above ground.
2. To convert tornado speeds from mi/h to m/s, multiply mapped values by 0.447.
3. Linear interpolation is permitted between contours. Point values (where shown) are provided to aid with interpolation.

Figure 32.5-1A. Tornado speeds for Risk Category III buildings and other structures, for effective plan area of 1 ft^2 (0.1 m^2).

@seismicisolation

4. Islands, coastal areas, and land boundaries outside the last contour shall use the last tornado speed contour.
5. Tornado speeds correspond to approximately a 3% probability of exceedance in 50 years (annual exceedance probability =0.000588, MRI = 1,700 years).
6. Location-specific tornado speed is permitted to be determined using the ASCE Tornado Design Geodatabase, available at the ASCE 7 Hazard Tool (http://asce7hazardtool.online) or approved equivalent.

Figure 32.5-1A (*Continued*). Tornado speeds for Risk Category III buildings and other structures, for effective plan area of 1 ft^2 (0.1 m^2).

Table 32.6-1. Tornado Directionality Factor, K_{dT}.

Structure Type	Tornado Directionality Factor, K_{dT}
Buildings	
Main wind force resisting system	0.80
Components and cladding	
For Essential Facilities and for buildings and other structures required to maintain the functionality of Essential Facilities	1.0
Roof Zone 1′ as shown in Figure 30.3-2A	0.90
All other cases	0.75
Arched roofs, circular domes, and all other structures	Use value from Table 26.6-1

Table 32.10-1. Tornado Velocity Pressure Exposure Coefficients, K_{zTor} and K_{hTor}.

Height above Ground Level, z or h		K_{zTor} and K_{hTor}
ft	m	
0–200	0–61.0	1.0
250	76.2	0.96
300	91.4	0.92
>328	>100	0.90

Notes:

1. The tornado velocity pressure exposure coefficient, K_{zTor}, is permitted to be determined as follows:
   For $0 < z \le 200$ ft (60 m) $K_{zTor} = 1.0$
   For $200 < z \le 328$ ft $K_{zTor} = [(2820 - z)/2620]^2$, where z is in ft
   (For $61 < z \le 100$ m) $K_{zTor} = [(861 - z)/800]^2$, where z is in m)
   For $z > 328$ ft (100 m) $K_{zTor} = 0.90$
2. Linear interpolation for intermediate values of height z is permitted.

Table 32.13-1. Main Wind Force Resisting System and Components and Cladding Tornado Internal Pressure Coefficient, (GC_{piT}).

Enclosure Classification	Criteria for Enclosure Classification	Internal Pressure Combined with Atmospheric Pressure Change	Tornado Internal Pressure Coefficient, (GC_{piT})
Sealed other structures	See Section 32.2	Extreme	+1.0
Enclosed buildings and other structures	See Table 26.13-1	High	+0.55 −0.18
Partially enclosed buildings and other structures	See Table 26.13-1	High	+0.55 −0.55
Partially open buildings and other structures	See Table 26.13-1	Moderate	+0.18 −0.18
Open buildings and other structures	See Table 26.13-1	Negligible	0.00

Notes:

1. Plus and minus signs signify pressures acting toward and away from the internal surfaces, respectively.
2. Values of (GC_{piT}) shall be used with q_z or q_h as specified.
3. Two cases shall be considered to determine the critical load requirements for the appropriate condition:
   (a) A positive value of (GC_{piT}) applied to all internal surfaces, or
   (b) A negative value of (GC_{piT}) applied to all internal surfaces.

@seismicisolation
@seismicisolation

32.13.1 Reduction Factor for Large-Volume Buildings, R_i For a partially enclosed building containing a single, unpartitioned large volume, the internal pressure coefficient, (GC_{piT}), is permitted to be multiplied by the reduction factor, R_i, as determined in Section 26.13.1.

32.14 TORNADO EXTERNAL PRESSURE COEFFICIENTS

External pressure coefficients C_p and (GC_p) shall be determined from the applicable sections of Chapters 27, 29, 30, and 31, and multiplied by the tornado pressure coefficient adjustment factor for vertical winds, K_{vT}, as specified in Table 32.14-1 and in accordance with Sections 32.15 through 32.17.

32.15 TORNADO LOADS ON BUILDINGS: MAIN WIND FORCE RESISTING SYSTEM

32.15.1 Enclosed, Partially Enclosed, and Partially Open Buildings Section 27.3.1 shall apply for determination of MWFRS loads for buildings of all heights, as modified in this section. Design tornado pressures, p_T, for the MWFRS of enclosed, partially enclosed, and partially open buildings of all heights shall be determined in accordance with the following equation, which replaces Equation (27.3-1):

$$p_T = qG_TK_{dT}K_{vT}C_p - q_i(GC_{piT}) \text{ (lb/ft}^2\text{)} \qquad (32.15\text{-}1)$$

$$p_T = qG_TK_{dT}K_{vT}C_p - q_i(GC_{piT}) \text{ (N/m}^2\text{)} \qquad (32.15\text{-}1.\text{SI})$$

where

$q = q_{zT}$ For external pressure on all walls evaluated at height z above the ground, lb/ft^2 (N/m^2),
$q = q_{hT}$ For external pressure on roofs evaluated at height h, lb/ft^2 (N/m^2),
$q_i = q_{hT}$ For internal pressure evaluation of roofs of enclosed and partially open buildings, lb/ft^2 (N/m^2),
$q_i = q_{zT}$ For internal pressure evaluation of walls of enclosed and partially open buildings, lb/ft^2 (N/m^2),
$q_i = q_{zop}$ For internal pressure evaluation of the roof and all walls in partially enclosed buildings, where height z_{op} is defined as the level of the lowest opening in the building that could affect the positive internal pressure, lb/ft^2 (N/m^2). Glazed openings not meeting the protection requirements of Section 32.12.3.1 shall be considered as openings,
G_T = Tornado gust-effect factor from Section 32.11,
K_{dT} = Tornado directionality factor from Section 32.6,
K_{vT} = Tornado pressure coefficient adjustment factor from Section 32.14,
C_p = External pressure coefficient from Section 27.3.1, and
(GC_{piT}) = Tornado internal pressure coefficient from Section 32.13.

32.15.1.1 Elevated Buildings Section 27.3.1.1 shall apply for determination of MWFRS loads on elevated buildings, as modified in this section. The design tornado pressure, p_T, for the effects of tornado pressure on the MWFRS shall be determined in accordance with Equation (32.15-1), where K_{vT} = 1.0 for lateral loads on elements below the elevated building and vertical loads on the horizontal bottom surfaces of the elevated building.

32.15.2 Open Buildings with Monoslope, Pitched, or Troughed Free Roofs Section 27.3.2 shall apply for determination of MWFRS loads on open buildings, as modified in this section. The net design tornado pressure, p_T, for the MWFRS of open buildings with monoslope, pitched, or troughed free roofs shall be determined in accordance with Section 27.3.2 and the following equation, which replaces Equation (27.3-2):

Table 32.14-1. Tornado Pressure Coefficient Adjustment Factor for Vertical Winds, K_{vT}.

STRUCTURE TYPE	K_{vT}
Buildings	
Negative (Uplift) Pressures on Roofs	
Main Wind Force Resisting System	1.1
Components and Cladding	
Roof slope ≤ 7 degrees

@seismicisolation

$$p_T = q_{hT} G_T K_{dT} C_N \text{ (lb/ft}^2\text{)} \quad (32.15\text{-}2)$$

$$p_T = q_{hT} G_T K_{dT} C_N \text{ (N/m}^2\text{)} \quad (32.15\text{-}2.SI)$$

where

q_{hT} = Tornado velocity pressure from Section 32.10.2 evaluated at mean roof height h, lb/ft^2 (N/m^2),
G_T = Tornado gust-effect factor from Section 32.11,
K_{dT} = Tornado directionality factor from Section 32.6, and
C_N = Net pressure coefficient from Section 27.3.2.

32.15.3 Roof Overhangs Section 27.3.3 shall apply for determination of MWFRS loads on roof overhangs.

32.15.4 Parapets Section 27.3.4 shall apply for determination of MWFRS loads on parapets, as modified in this section. The design tornado pressure, p_{pt}, for the effects of parapets on the MWFRS shall be determined in accordance with the following equation, which replaces Equation (27.3-3):

$$p_{pT} = q_{pT} K_{dT} (GC_{pn}) \text{ (lb/ft}^2\text{)} \quad (32.15\text{-}3)$$

$$p_{pT} = q_{pT} K_{dT} (GC_{pn}) \text{ (N/m}^2\text{)} \quad (32.15\text{-}3.SI)$$

where

p_{pT} = Combined net tornado design pressure on the parapet caused by the combination of the net pressures from the front and back parapet surfaces, lb/ft^2 (N/m^2). Plus (and minus) signs signify net pressure acting toward (and away from) the front (exterior) side of the parapet;
q_{pT} = Tornado velocity pressure from Section 32.10.2 evaluated at the top of the parapet, lb/ft^2 (N/m^2);
K_{dT} = Tornado directionality factor from Section 32.6; and
(GC_{pn}) = Combined net pressure coefficient from Section 27.3.4.

32.15.5 Design Load Cases The design load cases shall be determined using Section 27.3.5. The exception for buildings meeting the requirements of Section D1 of Appendix D shall not apply.

32.16 TORNADO LOADS ON BUILDING APPURTENANCES AND OTHER STRUCTURES: MAIN WIND FORCE RESISTING SYSTEM

32.16.1 General Requirements The design tornado speed in Section 32.5 for rooftop structures and equipment, including rooftop solar panels, shall equal that used for design of the building.

The effective plan area for freestanding walls and solid signs shall be equal to the wall or sign length squared divided by 20 but shall not be taken smaller than the length multiplied by the width. The length of the wall or sign shall be calculated as the distance between expansion joints.

32.16.2 Solid Freestanding Walls and Solid Signs Section 29.3 shall apply for determination of MWFRS loads on solid freestanding walls and solid signs, as modified in this section. The design tornado force, F_T, for solid freestanding walls and solid freestanding signs shall be determined in accordance with following equation, which replaces Equation (29.3-1):

$$F_T = q_{zT} G_T K_{dT} C_f A_s \text{ (lb)} \quad (32.16\text{-}1)$$

$$F_T = q_{zT} G_T K_{dT} C_f A_s \text{ (N)} \quad (32.16\text{-}1.SI)$$

where

q_{zT} = Tornado velocity pressure from Section 32.10.2 evaluated at the centroid of area, A_s, of the wall or sign, lb/ft2 (N/m^2);
G_T = Tornado gust-effect factor from Section 32.11;
K_{dT} = Tornado directionality factor from Section 32.6;
C_f = Net force coefficient from Figure 29.3-1; and
A_s = Gross area of the solid freestanding wall or freestanding solid sign, ft^2 (m^2).

32.16.3 Other Structures Section 29.4 shall apply for determination of MWFRS loads on other structures (chimneys, tanks, open signs, single-plane open frames, and trussed towers), as modified in this section. The design tornado force, F_T, for other structures, whether ground or roof mounted, shall be determined in accordance with the following equation, which replaces Equation (29.4-1):

$$F_T = q_{zT} G_T K_{dT} C_f A_f \text{ (lb)} \quad (32.16\text{-}2)$$

$$F_T = q_{zT} G_T K_{dT} C_f A_f \text{ (N)} \quad (32.16\text{-}2.SI)$$

where

q_{zT} = Tornado velocity pressure from Section 32.10.2 evaluated at height z, as defined in Section 26.10, of the centroid of area A_f, lb/ft^2 (N/m^2);
G_T = Tornado gust-effect factor from Section 32.11;
K_{dT} = Tornado directionality factor from Section 32.6;
C_f = Force coefficients from Section 29.4; and
A_f = Projected area normal to the tornadic wind from Section 29.4, ft^2 (m^2).

32.16.3.1 Trussed Towers Trussed towers and other open lattice-type structures shall be designed for an additional 40 ft^2 (3.7 m^2) of projected surface area of clinging debris at midheight of the structure or 50 ft (15 m), whichever is less.

32.16.3.2 Rooftop Structures and Equipment for Buildings Section 29.4.1 shall apply for determination of MWFRS loads on rooftop structures and equipment, as modified in this section. The lateral design tornado force, $\boldsymbol{F_{hT}}$, and vertical design tornado force, $\boldsymbol{F_{vT}}$, for rooftop structures and equipment, except as otherwise specified for roof-mounted solar panels (Sections 32.16.3.4 and 32.16.3.5) and structures identified in Section 32.16.3, shall be determined as follows.

The resultant lateral force, F_{hT}, shall be applied at a height above the roof surface equal to or greater than the centroid of the projected area, A_f, and determined in accordance with the following equation, which replaces Equation (29.4-2):

$$F_{hT} = q_{hT} K_{dT} (GC_r) A_f \text{ (lb)} \quad (32.16\text{-}3)$$

$$F_{hT} = q_{hT} K_{dT} (GC_r) A_f \text{ (N)} \quad (32.16\text{-}3.SI)$$

where

q_{hT} = Tornado velocity pressure from Section 32.10.2 evaluated at mean roof height h, lb/ft^2 (N/m^2),
K_{dT} = Tornado directionality factor from Section 32.6,
(GC_r) = Product of external pressure coefficient and gust-effect factor from Section 29.4.1, and
A_f = Vertical projected area of the rooftop structure or equipment from Section 29.4.1, ft^2 (m^2).

The vertical uplift design tornado force, F_{vT}, on rooftop structures and equipment shall be determined in accordance with the following equation, which replaces Equation (29.4-3):

@seismicisolation

$$F_{vT} = q_{hT} K_{dT} K_{vT} (GC_r) A_r \text{ (lb)} \quad (32.16\text{-}4)$$

$$F_{vT} = q_{hT} K_{dT} K_{vT} (GC_r) A_r \text{ (N)} \quad (32.16\text{-}4.SI)$$

where

q_{hT} = Tornado velocity pressure from Section 32.10.2 evaluated at mean roof height h, lb/ft^2 (N/m^2),
K_{dT} = Tornado directionality factor from Section 32.6,
K_{vT} = Tornado pressure coefficient adjustment factor from Section 32.14,
(GC_r) = Product of external pressure coefficient and gust-effect factor from Section 29.4.1, and
A_r = Horizontal projected area of rooftop structure or equipment, ft^2 (m^2).

32.16.3.3 Roofs of Isolated Circular Bins, Silos, and Tanks Section 29.4.2.2 shall apply for determination of MWFRS loads on the roofs of isolated circular bins, silos, and tanks, as modified in this section. The net design tornado pressures shall be determined in accordance with the following equation, which replaces Equation (29.4-4):

$$p_T = q_{hT}[G_T K_{dT} K_{vT} C_p - (GC_{piT})] \text{ (lb/ft}^2\text{)} \quad (32.16\text{-}5)$$

$$p_T = q_{hT}[G_T K_{dT} K_{vT} C_p - (GC_{piT})] \text{ (N/m}^2\text{)} \quad (32.16\text{-}5.SI)$$

where

q_{hT} = Tornado velocity pressure from Section 32.10.2 evaluated at mean roof height h, lb/ft^2 (N/m^2),
G_T = Tornado gust-effect factor from Section 32.11,
K_{dT} = Tornado directionality factor from Section 32.6,
K_{vT} = Tornado pressure coefficient adjustment factor from Section 32.14,
C_p = External pressure coefficient from Section 29.4.2.2, and
(GC_{piT}) = Tornado internal pressure coefficient from Section 32.13.

32.16.3.4 Rooftop Solar Panels for Buildings of All Heights with Flat Roofs or Gable or Hip Roofs with Slopes Less Than 7 Degrees Section 29.4.3 shall apply for determination of MWFRS loads on rooftop photovoltaic panels for buildings of all heights with flat roofs or gable or hip roofs with slopes less than 7 degrees, as modified in this section. The design tornado pressure, p_T, for rooftop photovoltaic panels shall be determined by the following equation, which replaces Equation (29.4-5):

$$p_T = q_{hT} K_{dT} (GC_{rn}) \text{ (lb/ft}^2\text{)} \quad (32.16\text{-}6)$$

$$p_T = q_{hT} K_{dT} (GC_{rn}) \text{ (N/m}^2\text{)} \quad (32.16\text{-}6.SI)$$

where

q_{hT} = Tornado velocity pressure from Section 32.10.2 evaluated at mean roof height h, lb/ft^2 (N/m^2),
K_{dT} = Tornado directionality factor from Section 32.6, and
(GC_{rn}) = Net pressure coefficient from Section 29.4.3.

32.16.3.5 Rooftop Solar Panels Parallel to the Roof Surface on Buildings of All Heights and Roof Slopes Section 29.4.4 shall apply for determination of MWFRS loads on rooftop photovoltaic panels parallel to the roof surface on buildings of all heights and roof slopes as modified in this section. The design tornado pressure, p_T, for rooftop photovoltaic panels shall be determined in accordance with the following equation, which replaces Equation (29.4-7):

$$p_T = q_{hT} K_{dT} K_{vT} (GC_p)(\gamma_E)(\gamma_a) \text{ (lb/ft}^2\text{)} \quad (32.16\text{-}7)$$

$$p_T = q_{hT} K_{dT} K_{vT} (GC_p)(\gamma_E)(\gamma_a) \text{ (N/m}^2\text{)} \quad (32.16\text{-}7.SI)$$

where

q_{hT} = Tornado velocity pressure from Section 32.10.2 evaluated at mean roof height h, lb/ft^2 (N/m^2);
K_{dT} = Tornado directionality factor from Section 32.6;
K_{vT} = Tornado pressure coefficient adjustment factor from Section 32.14;
(GC_p) = External pressure coefficient from Section 29.4.4;
γ_E = Array edge factor from Section 29.4.4; and
γ_a = Solar panel pressure equalization factor from Section 29.4.4.

32.17 TORNADO LOADS: COMPONENTS AND CLADDING

32.17.1 Low-Rise Buildings Section 30.3 shall apply for determination of component and cladding tornado loads on low-rise buildings, as modified in this section. The design tornado pressures, p_T, on C&C elements in low-rise buildings and buildings with $h \le 60$ ft ($h \le 18.3$ m) shall be determined in accordance with the following equation, which replaces Equation (30.3-1):

$$p_T = q_{hT}[K_{dT} K_{vT} (GC_p) - (GC_{piT})] \text{ (lb/ft}^2\text{)} \quad (32.17\text{-}1)$$

$$p_T = q_{hT}[K_{dT} K_{vT} (GC_p) - (GC_{piT})] \text{ (N/m}^2\text{)} \quad (32.17\text{-}1.SI)$$

where

q_{hT} = Tornado velocity pressure from Section 32.10.2 evaluated at mean roof height h, lb/ft^2 (N/m^2);
K_{dT} = Tornado directionality factor from Section 32.6;
K_{vT} = Tornado pressure coefficient adjustment factor from Section 32.14;
(GC_p) = External pressure coefficient from Section 30.3; and
(GC_{piT}) = Tornado internal pressure coefficient from Section 32.13.

32.17.1.1 Bottom Horizontal Surfaces of Elevated Buildings Section 30.3.2.1 shall apply for determination of C&C loads on bottom horizontal surfaces of elevated buildings, as modified in this section. The design tornado pressure, p_T, for the effects of tornado pressure on C&C shall be determined in accordance with Equation (32.17-1), where $K_{vT} = 1.0$.

32.17.2 Buildings with $h > 60$ ft ($h > 18.3$ m) Section 30.4 shall apply for the determination of component and cladding tornado loads on buildings with $h > 60$ ft ($h > 18.3$ m), as modified in this section. The design tornado pressures, p_T, on C&C elements for all buildings with $h > 60$ ft ($h > 18.3$ m) shall be determined in accordance with the following equation, which replaces Equation (30.4-1):

$$p_T = qK_{dT} K_{vT} (GC_p) - q_i (GC_{piT}) \text{ (lb/ft}^2\text{)} \quad (32.17\text{-}2)$$

$$p_T = qK_{dT} K_{vT} (GC_p) - q_i (GC_{piT}) \text{ (N/m}^2\text{)} \quad (32.17\text{-}2.SI)$$

where

$q = q_{zT}$ For external pressure on all walls evaluated at height z above the ground, lb/ft^2 (N/m^2);

@seismicisolation

q = For external pressures on roofs evaluated at height h, lb/ft^2 (N/m^2);
$q_i = q_{hT}$ For internal pressure evaluation of roofs of enclosed and partially open buildings, lb/ft^2 (N/m^2);
$q_i = q_{zT}$ For internal pressure evaluation of walls of enclosed and partially open buildings, lb/ft^2 (N/m^2);
$q_i = q_{zop}$ For internal pressure evaluation of the roof and all walls in partially enclosed buildings, where height z_{op} is defined as the level of the lowest opening in the building that could affect the positive internal pressure, lb/ft^2 (N/m^2). Glazed openings not meeting the protection requirements of Section 32.12.3.1 shall be considered as openings;
K_{dT} = Tornado directionality factor from Section 32.6;
K_{vT} = Tornado pressure coefficient adjustment factor from Section 32.14;
(GC_p) = External pressure coefficient from Section 30.4; and
(GC_{piT}) = Tornado internal pressure coefficient from Section 32.13.

32.17.2.1 Bottom Horizontal Surfaces of Elevated Buildings Section 30.5.2.1 shall apply for determination of C&C loads on bottom horizontal surfaces of elevated buildings, as modified in this section. The design tornado pressure, p_T, for the effects of tornado pressure on C&C shall be determined in accordance with Equation (32.17-1), where K_{vT} = 1.0, and the tornado velocity pressure, q, shall be calculated at the height specified in Section 30.5.2.1, subparagraph 1.

32.17.3 Open Buildings Section 30.5 shall apply for the determination of component and cladding tornado loads on open buildings, as modified in this section. The net tornado design pressures, p_T, for C&C elements of open buildings of all heights shall be determined in accordance with the following equation, which replaces Equation (30.5-1):

$$p_T = q_{hT} G_T K_{dT} C_N \text{ (lb/ft}^2\text{)} \quad (32.17\text{-}3)$$

$$p_T = q_{hT} G_T K_{dT} C_N \text{ (N/m}^2\text{)} \quad (32.17\text{-}3.\text{SI})$$

where

q_{hT} = Tornado velocity pressure from Section 32.10.2 evaluated at mean roof height h, lb/ft^2 (N/m^2);
G_T = Tornado gust-effect factor from Section 32.11;
K_{dT} = Tornado directionality factor from Section 32.6; and
C_N = Net pressure coefficient from Section 30.5.

32.17.4 Building Appurtenances and Rooftop Structures and Equipment

32.17.4.1 Parapets Section 30.6 shall apply for determination of component and cladding tornado loads on parapets, as modified in this section. The design tornado pressures, p_T, on C&C elements of parapets for all building types and heights shall be determined in accordance with the following equation, which replaces Equation (30.6-1):

$$p_T = q_{pT}[K_{dT}(GC_p) - (GC_{piT})] \text{(lb/ft}^2\text{)} \quad (32.17\text{-}4)$$

$$p_T = q_{pT}[K_{dT}(GC_p) - (GC_{piT})] \text{ (N/m}^2\text{)} \quad (32.17\text{-}4.\text{SI})$$

where

q_{pT} = Tornado velocity pressure from Section 32.10.2 evaluated at the top of the parapet, lb/ft^2 (N/m^2);
K_{dT} = Tornado directionality factor from Section 32.6;
(GC_p) = External pressure coefficient from Section 30.8; and
(GC_{piT}) = Tornado internal pressure coefficient from Section 32.13, based on the porosity of the parapet envelope.

32.17.4.2 Roof Overhangs Section 30.7 shall apply for determination of component and cladding tornado loads on roof overhangs, as modified in this section. The design tornado pressures, p_T, on C&C elements of roof overhangs for all building types and heights shall be determined in accordance with the following equation, which replaces Equation (30.7-1):

$$p_T = q_{hT}[K_{dT}K_{vT}(GC_p) - (GC_{piT})] \text{ (lb/ft}^2\text{)} \quad (32.17\text{-}5)$$

$$p_T = q_{hT}[K_{dT}K_{vT}(GC_p) - (GC_{piT})] \text{ (N/m}^2\text{)} \quad (32.17\text{-}5.\text{SI})$$

where

q_{hT} = Tornado velocity pressure from Section 32.10.2 evaluated at mean roof height h, lb/ft^2 (N/m^2);
K_{dT} = Tornado directionality factor from Section 32.6;
K_{vT} = Tornado pressure coefficient adjustment factor from Section 32.14;
(GC_p) = External pressure coefficient from Section 30; and
(GC_{piT}) = Tornado internal pressure coefficient from Section 32.13, based on the porosity of the parapet envelope.

32.17.4.3 Attached Canopies on Buildings with $h \le 60$ ft ($h \le 18.3$ m) Section 30.9 shall apply for determination of component and cladding tornado loads on attached canopies on buildings with $h \le 60$ ft ($h \le 18.3$ m), as modified in this section. The design tornado pressures, p_T, on C&C elements of attached canopies shall be determined in accordance with the following equation, which replaces Equation (30.9-1):

$$p_T = q_{hT} K_{dT} (GC_p) \text{ (lb/ft}^2\text{)} \quad (32.17\text{-}6)$$

$$p_T = q_{hT} K_{dT} (GC_p) \text{ (N/m}^2\text{)} \quad (32.17\text{-}6.\text{SI})$$

where

q_{hT} = Tornado velocity pressure from Section 32.10.2 evaluated at mean roof height h, lb/ft^2 (N/m^2);
K_{dT} = Tornado directionality factor from Section 32.6; and
(GC_p) = Net pressure coefficient from Section 30.9.

32.17.5 Nonbuilding Structures Section 30.10 shall apply for determination of component and cladding tornado loads on circular bins, silos, and tanks with $h \le 120$ ft ($h \le 36.6$ m), as modified in this section.

32.17.5.1 Isolated Circular Bins, Silos, and Tanks The design tornado pressures, p_T, on C&C elements of isolated circular bins, silos and tanks shall be determined in accordance with the following equation, which replaces Equation (30.10-1):

$$p_T = q_{hT}[K_{dT}K_{vT}(GC_p) - (GC_{piT})] \text{ (lb/ft}^2\text{)} \quad (32.17\text{-}7)$$

$$p_T = q_{hT}[K_{dT}K_{vT}(GC_p) - (GC_{piT})] \text{ (N/m}^2\text{)} \quad (32.17\text{-}7.\text{SI})$$

where

q_{hT} = Tornado velocity pressure from Section 32.10.2 evaluated at mean roof height h, lb/ft^2 (N/m^2);
K_{dT} = Tornado directionality factor from Section 32.6;
K_{vT} = Tornado pressure coefficient adjustment factor. The roof slope for determination of K_{vT} shall be as defined in Figure 30.12-2:

@seismicisolation
@seismicisolation

(1) For roof zones 1 and 2 in Figure 30.12-2, K_{vT} shall equal the Zone 1 value for building roofs from Table 32.14-1, and
(2) For roof zones 3 and 4 in Figure 30.12-2, K_{vT} shall equal the Zone 2 value for building roofs from Table 32.14-1;

(GC_p) = External pressure coefficient from Section 30.10; and
(GC_{piT}) = Tornado internal pressure coefficient, as follows:

(1) For internal surface of exterior walls of isolated open-topped circular bins, silos, and tanks, use (GC_{piT}) from Section 30.12.3, and
(2) In all other cases, use (GC_{piT}) from Section 32.13.

32.18 TORNADO LOADS: WIND TUNNEL PROCEDURE

The wind tunnel procedure, as described in Chapter 31, is permitted for determination of external pressure coefficients and force coefficients for use with the tornado loading provisions of Sections 32.15 through 32.17. The wind tunnel test shall be performed on an isolated building model (without a proximity model) in a boundary layer wind tunnel for open (Exposure C) terrain.

32.19 CONSENSUS STANDARDS AND OTHER REFERENCED DOCUMENTS

This section lists the consensus standards and other documents that shall be considered part of this standard to the extent referenced in this chapter.

ASTM E1886. 2019. *Standard Test Method for Performance of Exterior Windows, Curtain Walls, Doors, and Impact Protective Systems Impacted by Missile(s) and Exposed to Cyclic Pressure Differentials*. ASTM International.

Cited in: Section 32.12.3.1

ASTM E1996. 2020. *Standard Specification for Performance of Exterior Windows, Curtain Walls, Doors, and Impact Protective Systems Impacted by Windborne Debris in Hurricanes.* ASTM International.

APPENDIX C
SERVICEABILITY CONSIDERATIONS

C.1 SERVICEABILITY CONSIDERATIONS

This appendix is not a mandatory part of the standard but provides guidance for design for serviceability to maintain the function of a building and the comfort of its occupants during normal usage. Serviceability limits (e.g., maximum static deformations or accelerations) shall be chosen with due regard to the intended function of the structure.

Serviceability shall be checked using appropriate loads for the limit state being considered.

C.2 DEFLECTION, DRIFT, AND VIBRATION

C.2.1 Vertical Deflections Deformations of floor and roof members and systems caused by service loads shall not impair the serviceability of the structure.

C.2.2 Drift of Walls and Frames Lateral deflection or drift of structures and deformation of horizontal diaphragms and bracing systems caused by wind effects shall not impair the serviceability of the structure.

C.2.3 Vibrations Floor systems supporting large open areas free of partitions or other sources of damping, where vibration caused by pedestrian traffic might be objectionable, shall be designed with due regard for such vibration.

Mechanical equipment that can produce objectionable vibrations in any portion of an inhabited structure shall be isolated to minimize the transmission of such vibrations to the structure.

Building structural systems shall be designed so that wind-induced vibrations do not cause occupant discomfort or damage to the building, its appurtenances, or contents.

C.3 DESIGN FOR LONG-TERM DEFLECTION

Where required for acceptable building performance, members and systems shall be designed to accommodate long-term irreversible deflections under sustained load.

C.4 CAMBER

Special camber requirements that are necessary to bring a loaded member into proper relation with the work of other trades shall be set forth in the design documents.

Beams detailed without specified camber shall be positioned during erection so that any minor camber is upward. If camber involves the erection of any member under preload, this shall be noted in the design documents.

C.5 EXPANSION AND CONTRACTION

Dimensional changes in a structure and its elements caused by variations in temperature, relative humidity, or other effects shall not impair the serviceability of the structure.

Provision shall be made either to control crack widths or to limit cracking by providing relief joints.

C.6 DURABILITY

Buildings and other structures shall be designed to tolerate long-term environmental effects or shall be protected against such effects.

APPENDIX D
BUILDINGS EXEMPTED FROM TORSIONAL WIND LOAD CASES

D.1 SCOPE

The torsional load cases in Figure 27.3-8 (Case 2 and Case 4) need not be considered for a building meeting the conditions of Sections D.2, D.3, D.4, or D.5 if it can be shown by other means that the torsional load cases of Figure 27.3-8 do not control the design.

D.2 ONE- AND TWO-STORY BUILDINGS MEETING THE FOLLOWING REQUIREMENTS

One-story buildings with h less than or equal to 30 ft (9.2 m), buildings two stories or fewer framed with light-frame construction, and buildings two stories or fewer designed with flexible diaphragms are exempted.

D.3 BUILDINGS CONTROLLED BY SEISMIC LOADING

D.3.1 Buildings with Diaphragms at Each Level That Are Not Flexible Building structures that are regular under seismic load (as defined in Section 12.3.2) and conform to the following are exempted:

1. Eccentricity between the center of mass and the geometric centroid of the building at that level shall not exceed 15% of the overall building width along each principal axis considered at each level, and
2. Design story shear determined for earthquake load, as specified in Chapter 12, at each floor level shall be at least 1.5 times the design story shear determined for wind loads as specified herein.

The design earthquake and wind load cases considered when evaluating this exception shall be the load cases without torsion.

D.3.2 Buildings with Diaphragms at Each Level That Are Flexible Building structures that are regular under seismic load (as defined in Section 12.3.2) and conform to the following are exempted:

1. Design earthquake shear forces resolved to the vertical elements of the lateral load-resisting system shall be at least 1.5 times the corresponding design wind shear forces resisted by those elements.

The design earthquake and wind load cases considered when evaluating this exception shall be the load cases without torsion.

D.4 BUILDINGS CLASSIFIED AS TORSIONALLY REGULAR UNDER WIND LOAD

Buildings meeting the definition of torsionally regular buildings under wind load contained in Section 26.2 are exempted.

EXCEPTION: If a building does not qualify as being torsionally regular under wind load, it is permissible to base the design on the basic wind load Case 1 that is proportionally increased so that the maximum displacement at each level is not less than the maximum displacement for the torsional load Case 2.

D.5 BUILDINGS WITH DIAPHRAGMS THAT ARE FLEXIBLE AND DESIGNED FOR INCREASED WIND LOADING

The torsional wind load cases need not be considered if the design wind pressure in Cases 1 and 3 of Figure 27.3-8 is increased by a factor of 1.5.

APPENDIX E
PERFORMANCE-BASED DESIGN PROCEDURES FOR FIRE EFFECTS ON STRUCTURES

E.1 SCOPE

This appendix is not a mandatory part of the standard. It provides procedures for performance-based design and evaluation of structures for fire conditions that result in fire-induced effects on a structure's members and connections. The use of performance-based structural fire design procedures constitutes an alternative methodology to meet project design requirements, as is permitted by Section 1.3.7 and the alternative materials, design, and methods of construction provision in the building codes. This appendix does not provide for standard fire resistance design with prescriptive methods, nor does it address explosions.

E.2 DEFINITIONS

The following definitions apply to the information presented in this appendix.

FIRE: An oxidation process that results in the burning of flammable materials and produces heat.

FIRE EFFECTS: Thermal and structural response caused by fire exposure and subsequent cooling.

FIRE EXPOSURE: The extent to which materials, products, or assemblies are subjected to the conditions created by fire.

FIRE RESISTANCE: The ability of a material, product, or assembly to withstand fire or provide protection from it for a period of time.

FUEL LOAD: The total quantity of combustible contents within a building, space, or area, expressed either as total energy or as equivalent mass.

HEAT TRANSFER: The exchange of thermal energy caused by a temperature difference.

PERFORMANCE-BASED STRUCTURAL FIRE DESIGN: The explicit design of structural members and connections to satisfy performance objectives for structural design fires.

STANDARD FIRE RESISTANCE DESIGN: The selection of fire-resistive assemblies to meet code requirements for structural fire resistance (also known as prescriptive design). The rating of a fire-resistive assembly is based on its performance in standard fire testing.

STRUCTURAL DESIGN FIRE: A fire that has the potential to affect the integrity and stability of a structure that is used for the design and evaluation of the structure.

THERMAL BOUNDARY CONDITION: The temperature and/or heat flux to which an assembly or the structure is subjected during or after fire exposure based on the radiative and convective heating and/or cooling conditions at exposed surfaces.

THERMAL INSULATION: A material or medium that reduces the heat transfer between objects in thermal contact or in range of radiative or convective influence.

THERMAL RESPONSE: The temperature distribution of members and connections when exposed to thermal boundary conditions.

THERMAL RESTRAINT: A condition in which thermal expansion or contraction of structural members is resisted by forces external to the members. The level of restraint depends on the adjacent framing and connection details.

E.3 GENERAL REQUIREMENTS

Performance-based structural fire design and evaluation procedures shall comply with the requirements of Section 1.3.1.3.

Design and evaluation of structures for fire effects shall include the following tasks: identify performance objectives, quantify the fuel load, identify and evaluate structural design fires, determine temperature histories of structural members and connections, and determine the response of the structure. These tasks shall include evaluating the heating and subsequent cooling of the structure under fire exposure, as appropriate.

The structural response shall be evaluated against limit states based on the performance objectives. The analyses shall account for temperature-dependent material properties, boundary conditions, and thermally induced failure modes and shall evaluate structural stability, strength, deformation, and load path continuity.

E.4 PERFORMANCE OBJECTIVES

Performance objectives shall be expressed as quantifiable metrics for the design and evaluation of structural response to structural design fires. Performance objectives for structural integrity, including strength, stiffness, and stability, shall meet the minimum criteria specified in Section E.4.1. Additional project-specific performance objectives shall meet the requirements in Section E.4.2.

E.4.1 Structural Integrity Structural integrity shall be provided for buildings and other structures subject to structural design fires such that the structural system remains stable with a continuous load path to the extent necessary to ensure occupant life safety.

The performance of the structural system under structural design fires shall allow building occupants to travel safely to refuge areas within the building or exit the building to a public way. Structural support of building egress routes shall be maintained for a period of time necessary to ensure a safe and complete evacuation of building occupants. Structural support of building refuge areas shall be maintained throughout the heating and cooling of the structure.

@seismicisolation

E.4.2 Project-Specific Performance Objectives Buildings and other structures shall be designed to meet project-specific performance objectives required by the owner, Authority Having Jurisdiction, or applicable building code in addition to those in Section E.4.1.

E.5 THERMAL ANALYSIS OF FIRE EFFECTS

The thermal response of structural members and connections during and after structural design fires shall be determined for input to the structural analyses of fire effects.

E.5.1 Fuel Load The fuel load shall be quantified for use in the evaluation of structural design fires.

E.5.2 Structural Design Fires Structural design fires shall be identified and used to develop time-dependent thermal boundary conditions for use in heat transfer analyses.

E.5.3 Heat Transfer Analysis The temperature history of structural members and connections shall be determined using heat transfer analysis methods based on the time-dependent thermal boundary conditions for structural design fires.

Temperature-dependent thermal properties of materials comprising the structural system and thermal insulation shall be used in heat transfer analyses to determine the thermal response. It shall be permissible to use constant thermal property values if they yield conservative results.

E.6 STRUCTURAL ANALYSIS OF FIRE EFFECTS

Structural analyses shall include portions of the structural system that are subject to fire effects from the structural design fires as determined in Section E.5, with consideration of unheated portions of the structural system that provide thermal restraint. It is permissible for the analyses to consider alternate load paths that are capable of being maintained following structural damage or degradation caused by fire effects.

E.6.1 Temperature History for Structural Members and Connections Temperature histories for structural members and connections shall be determined from thermal analysis of structural design fires and shall be used to analyze fire effects on structural performance.

E.6.2 Temperature-Dependent Properties Temperature-dependent properties of structural materials shall be used to determine the performance of structural members and connections subject to structural design fires.

E.6.3 Load Combinations Load combinations in Section 2.5 for extraordinary events shall be used for analysis of fire effects and shall include time- and sequence-dependent effects. To check the residual capacity of a structure damaged by a structural design fire, the approach identified in Section 2.5.2.2 shall be used.

@seismicisolation

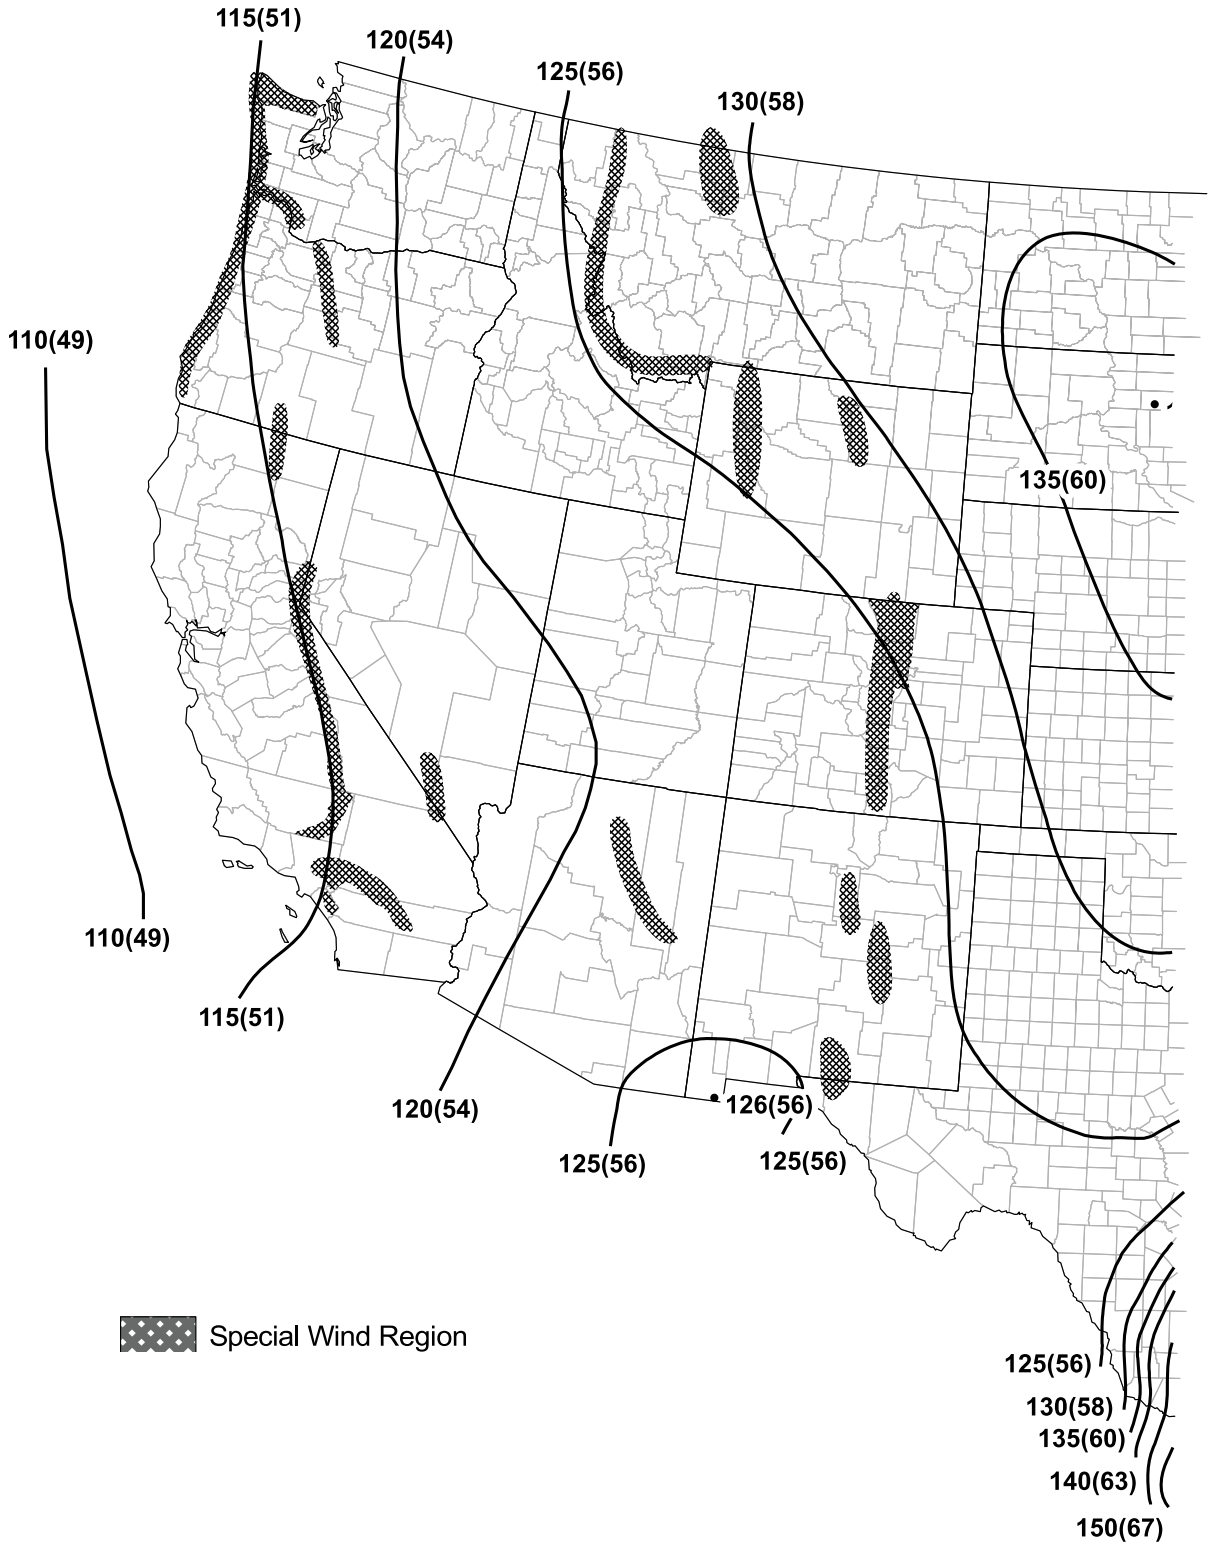
APPENDIX F
WIND HAZARD MAPS FOR LONG RETURN PERIODS

F.1 SCOPE

This appendix provides wind hazard maps for longer mean recurrence intervals (MRIs) than included in Chapter 26.

F.2 WIND SPEEDS



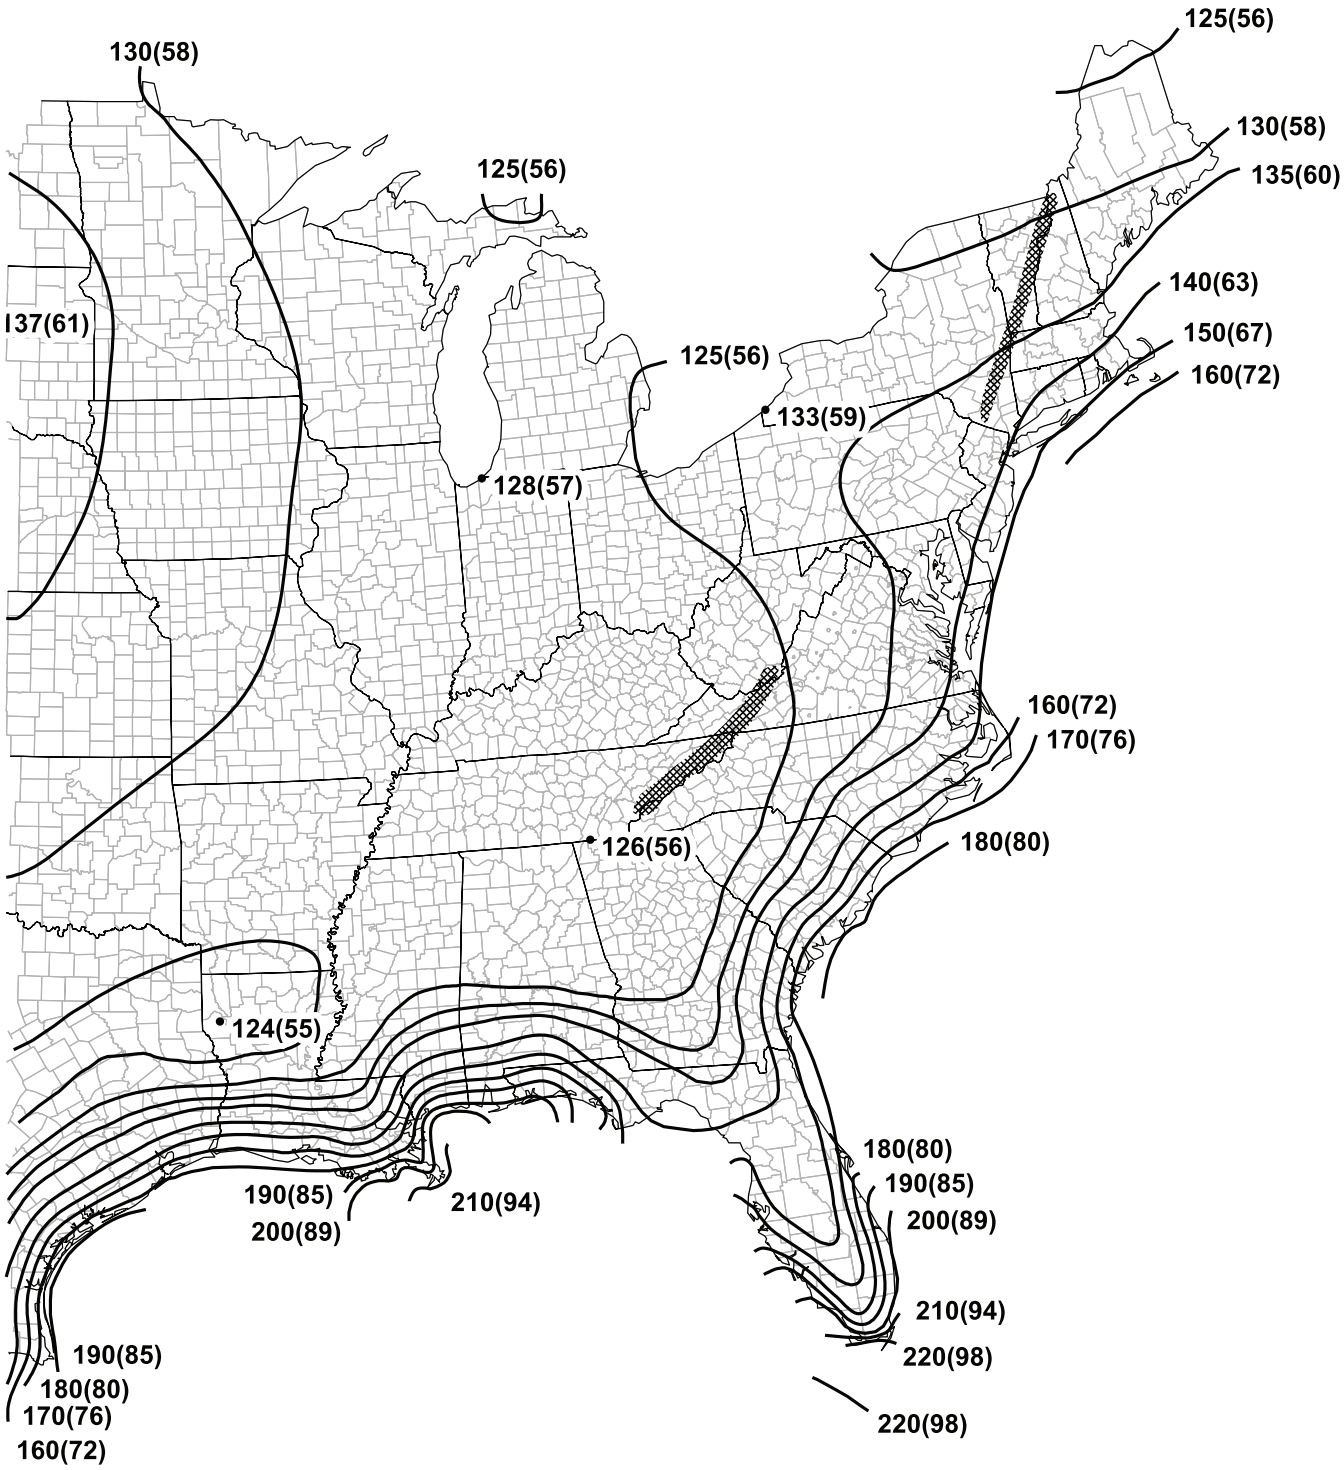
Except as provided in Sections 26.5.2 and 26.5.3, it shall be permitted to determine the wind speed used for design wind loads on buildings and other structures from Figures F.2-1 through F.2-3 as follows:

For 10,000-year MRI, use Figure F.2-1.
For 100,000-year MRI, use Figure F.2-2.
For 1,000,000-year MRI, use Figure F.2-3.

Alternatively, it shall be permitted to use the wind speed from the ASCE Wind Design Geodatabase for the contiguous United States.

User Note: The ASCE Wind Design Geodatabase is available at the ASCE 7 Hazard Tool (https://asce7hazardtool.online/), or approved equivalent.

@seismicisolation
@seismicisolation

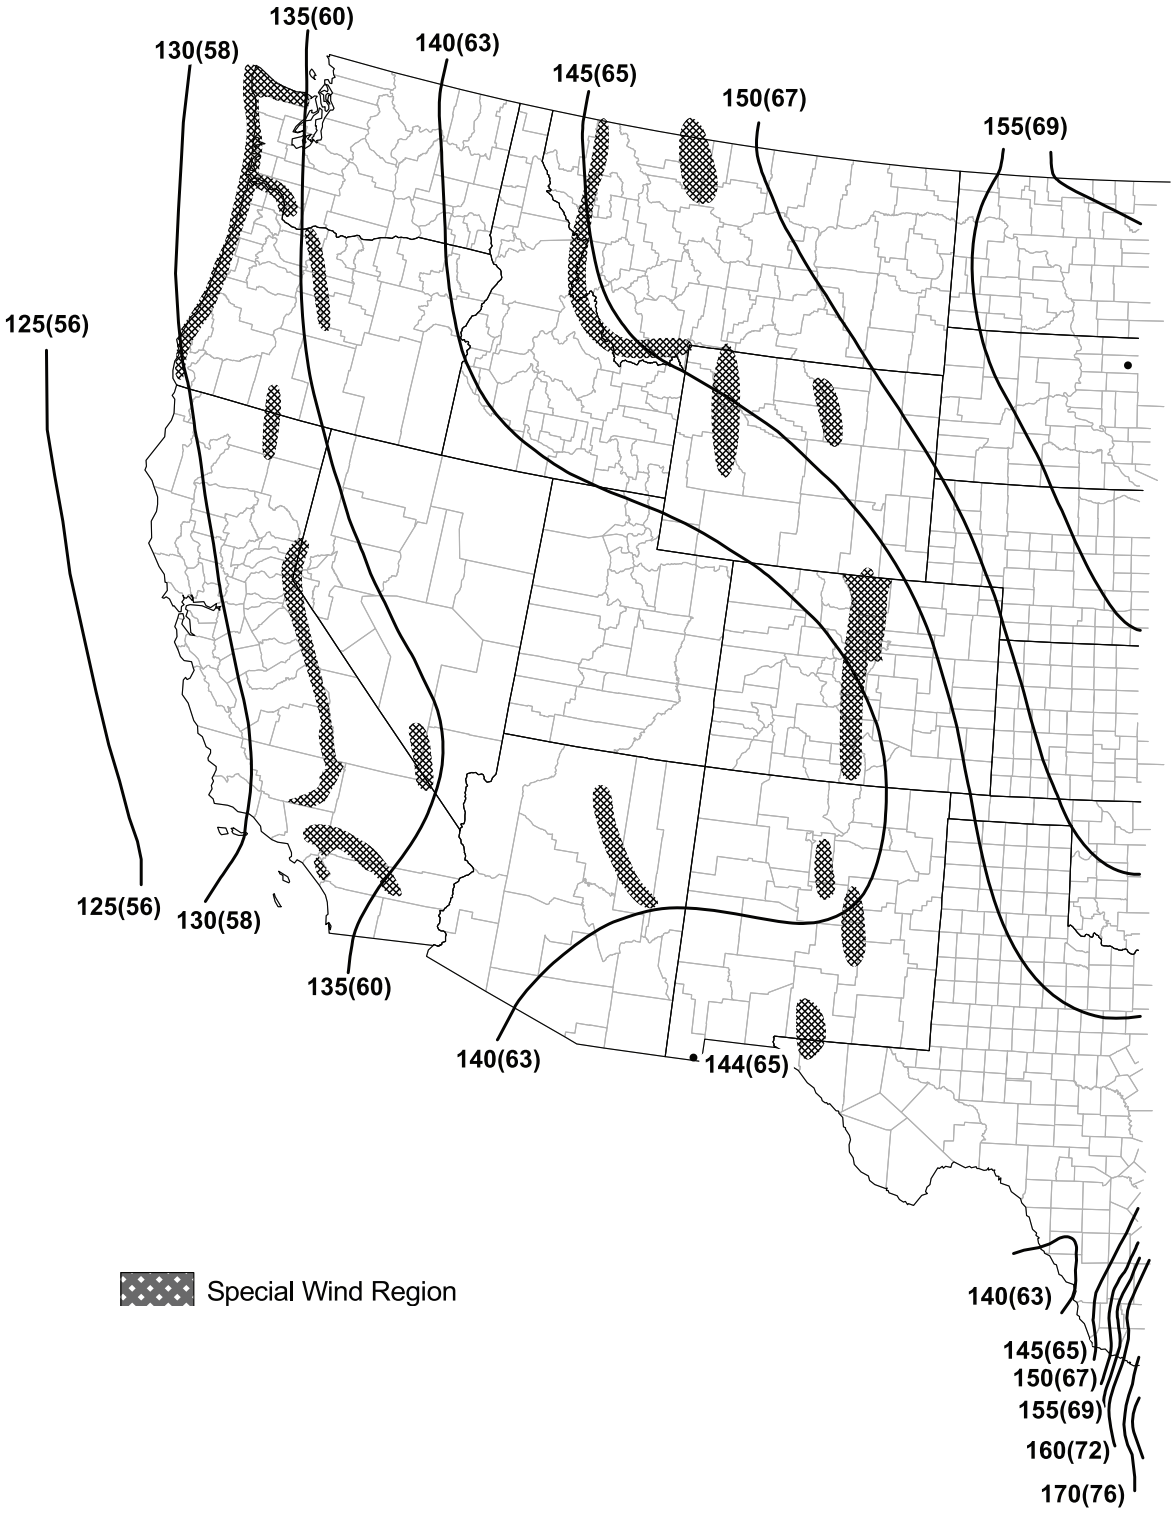


Notes:

1. Values are 3 s gust wind speeds in mi/h (m/s) at 33 ft (10 m) above ground for Exposure Category C.
2. Linear interpolation is permitted between contours. Point values are provided to aid with interpolation.
3. Islands, coastal areas, and land boundaries outside the last contour shall use the last wind speed contour.
4. Location-specific basic wind speeds shall be permitted to be determined using the ASCE Wind Design Geodatabase.

Figure F.2-1. 10,000-Year MRI gust wind speed, mi/h (m/s).

@seismicisolation



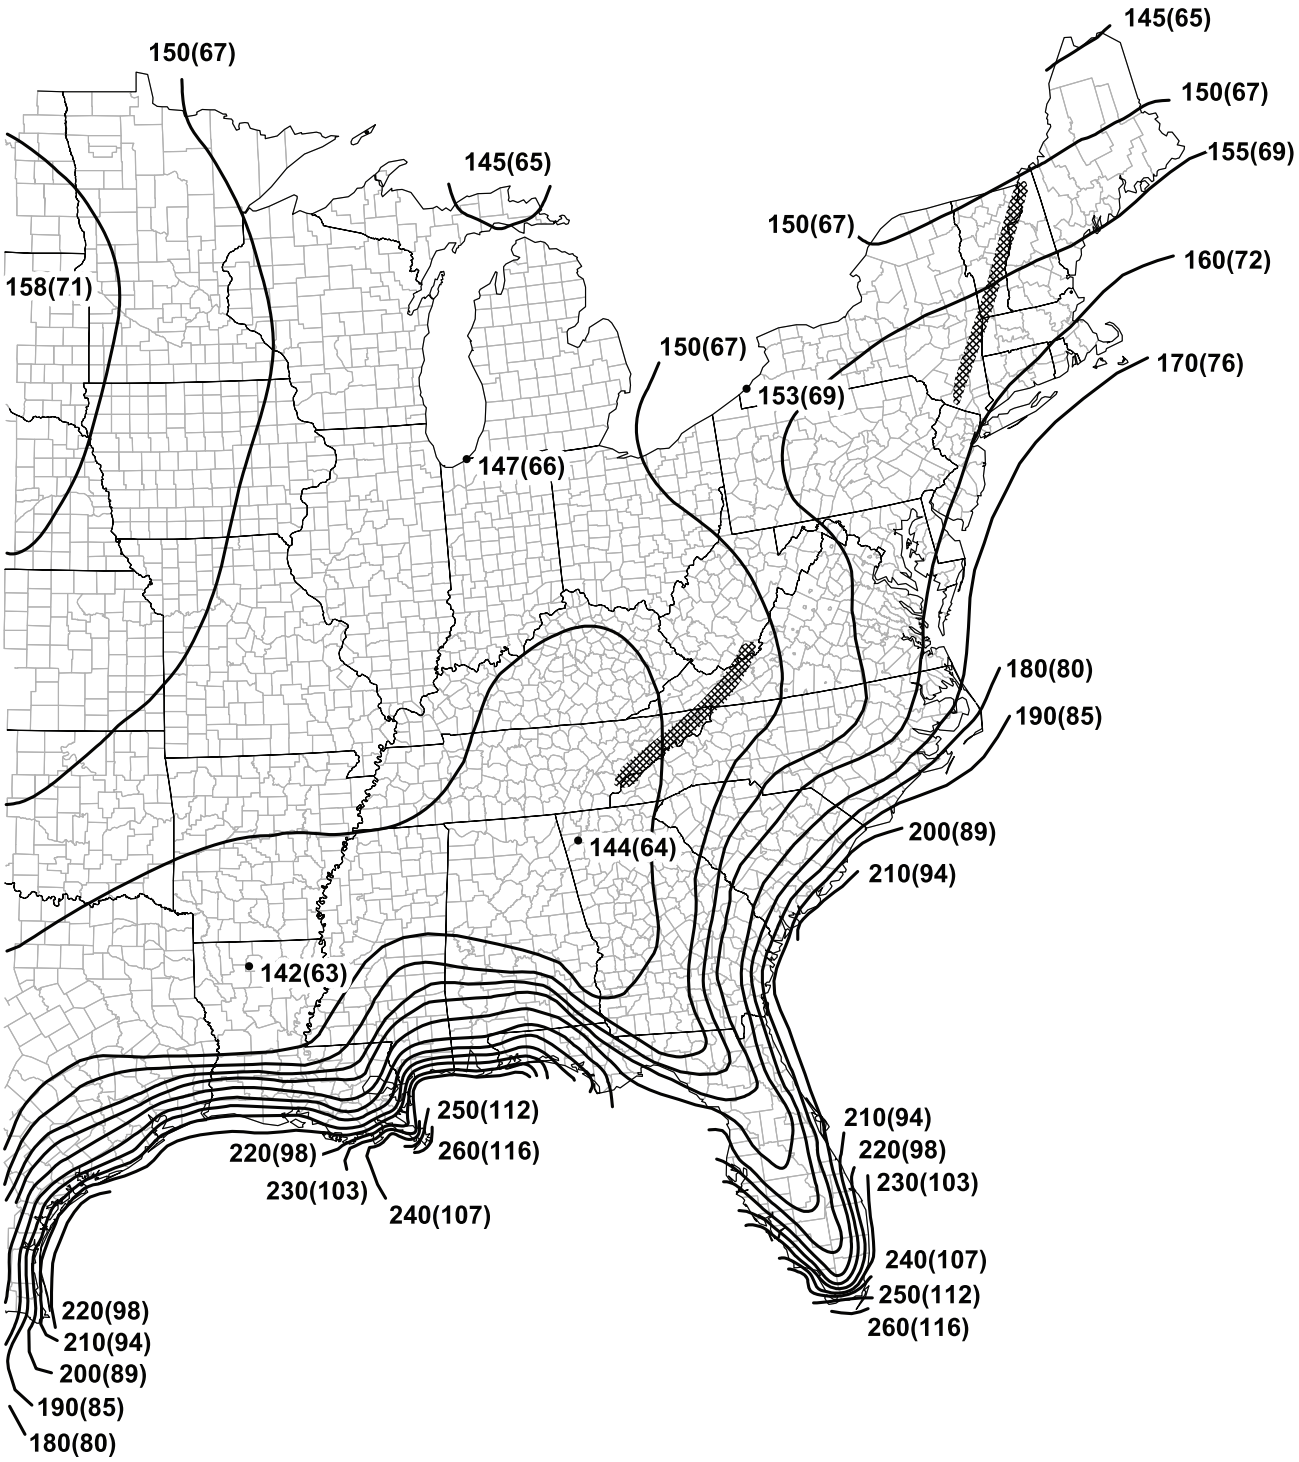
5. Mountainous terrain, gorges, ocean promontories, and special wind regions shall be examined for unusual wind conditions.

6. Wind speeds correspond to approximately a 0.5% probability of exceedance in 50 years (Annual Exceedance Probability = 0.0001, MRI = 10,000 years).

7. The ASCE Wind Design Geodatabase is available at the ASCE 7 Hazard Tool (https://asce7hazardtool.online), or approved equivalent.

Figure F.2-1. (*Continued*) 10,000-Year MRI gust wind speed, mi/h (m/s).

@seismicisolation

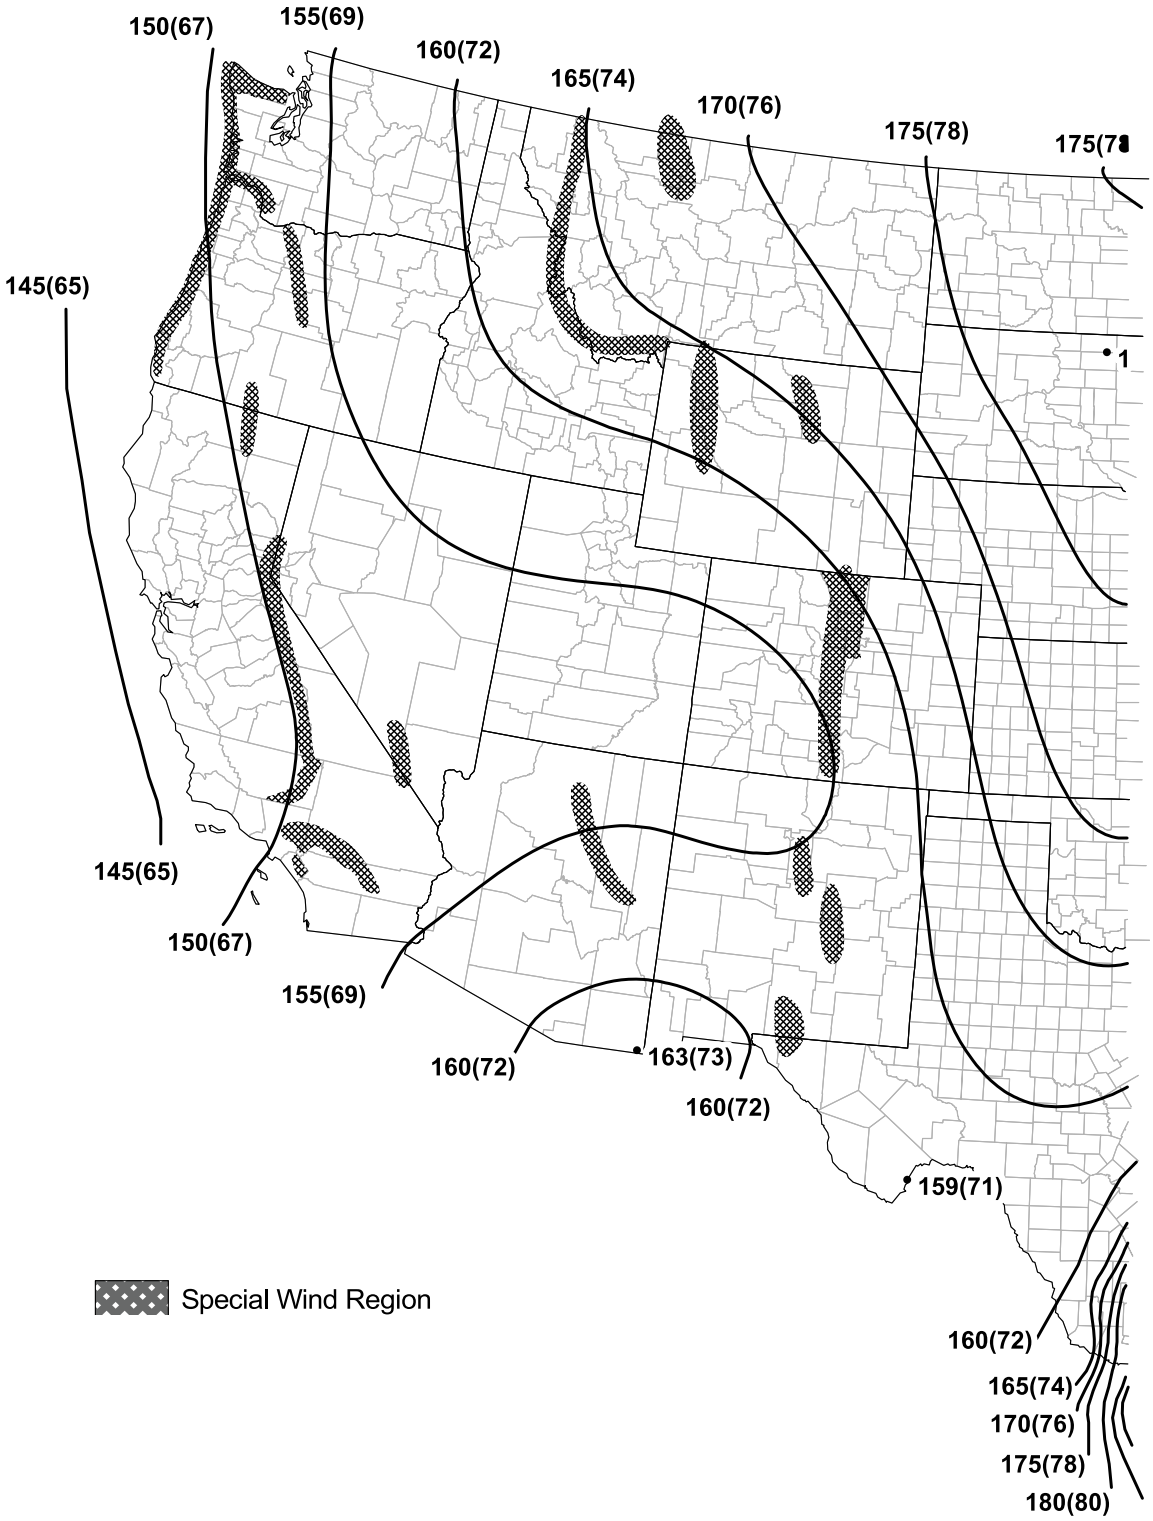


Notes:

1. Values are 3 s gust wind speeds in mi/h (m/s) at 33 ft (10 m) above ground for Exposure Category C.
2. Linear interpolation is permitted between contours. Point values are provided to aid with interpolation.
3. Islands, coastal areas, and land boundaries outside the last contour shall use the last wind speed contour.
4. Location-specific basic wind speeds shall be permitted to be determined using the ASCE Wind Design Geodatabase.

Figure F.2-2. 100,000-Year MRI gust wind speed, mi/h (m/s).

@seismicisolation



5. Mountainous terrain, gorges, ocean promontories, and special wind regions shall be examined for unusual wind conditions.

6. Wind speeds correspond to approximately a 0.5% probability of exceedance in 50 years (Annual Exceedance Probability = 0.00001, MRI = 100,000 years).

7. The ASCE Wind Design Geodatabase is available at the ASCE 7 Hazard Tool (https://asce7hazardtool.online), or approved equivalent.

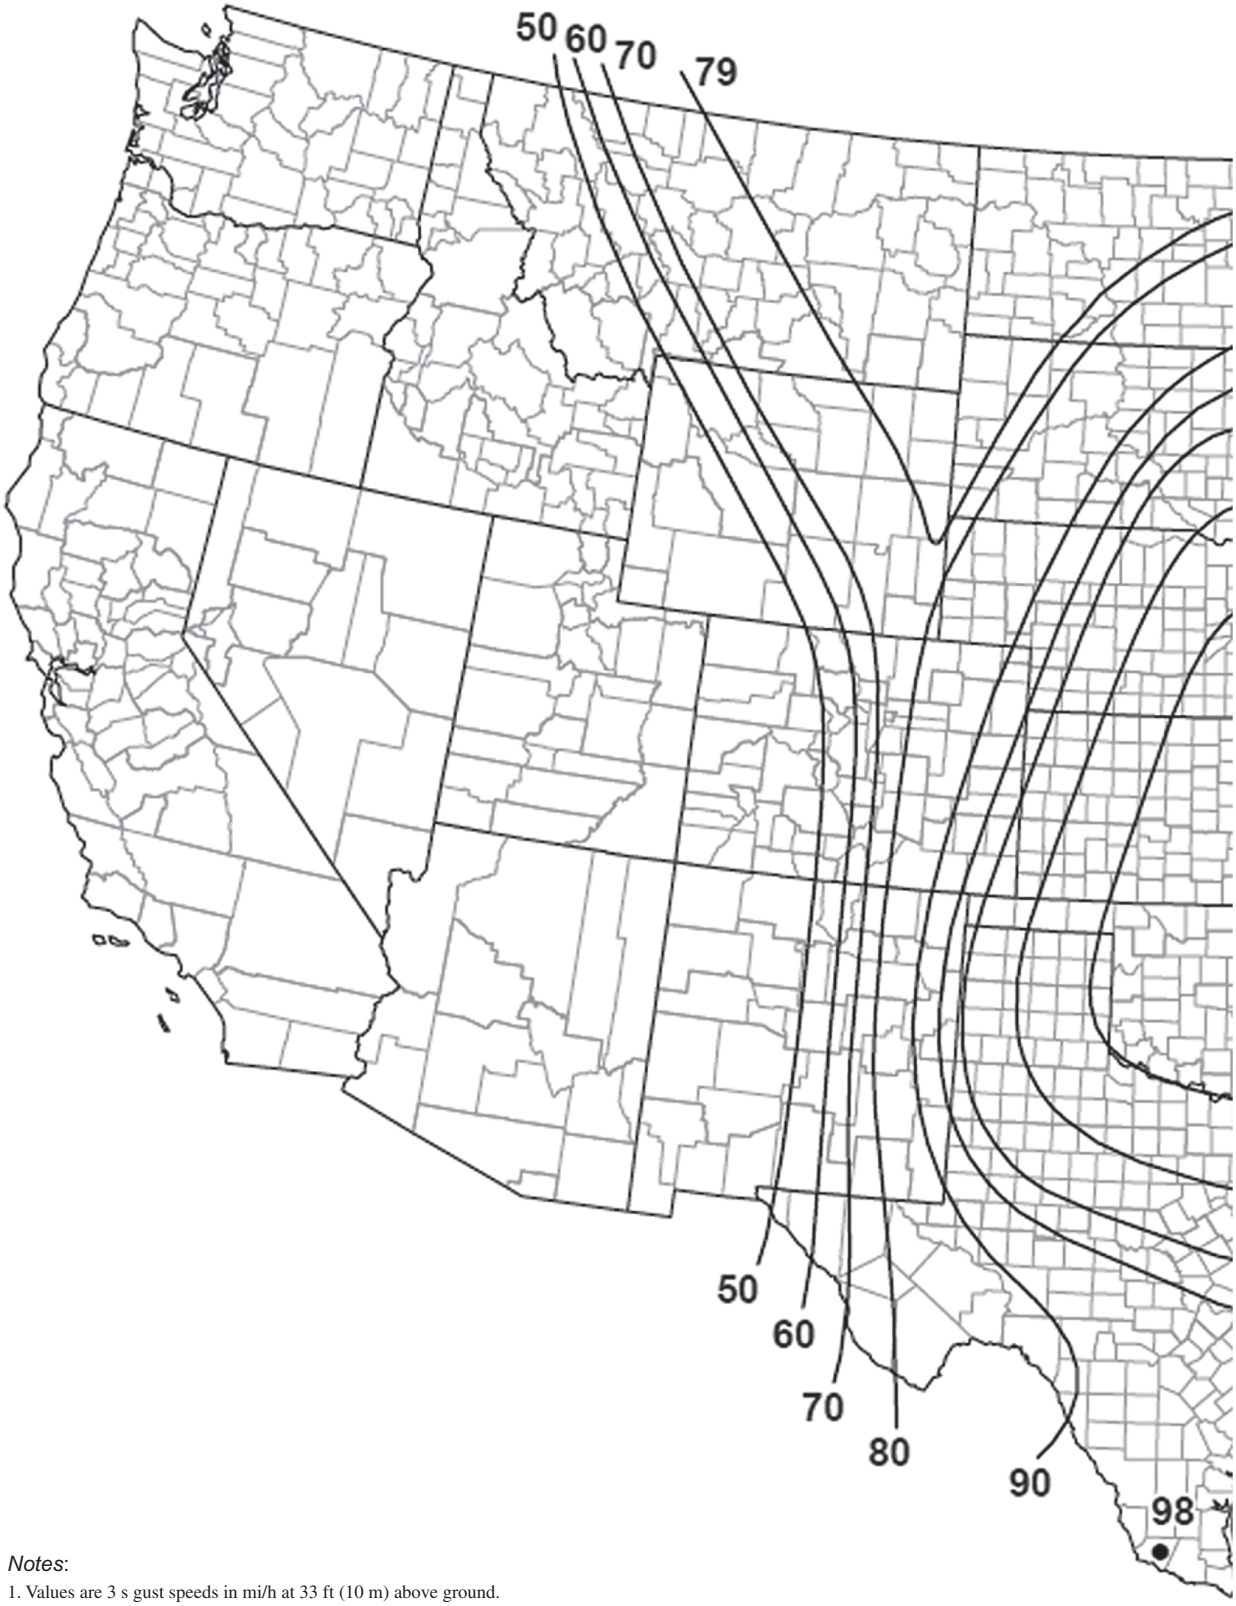
APPENDIX G
TORNADO HAZARD MAPS FOR LONG RETURN PERIODS

G.1 SCOPE

This appendix is not a mandatory part of the standard. This appendix provides tornado hazard maps for longer mean recurrence intervals (MRI) than those included in Chapter 32.



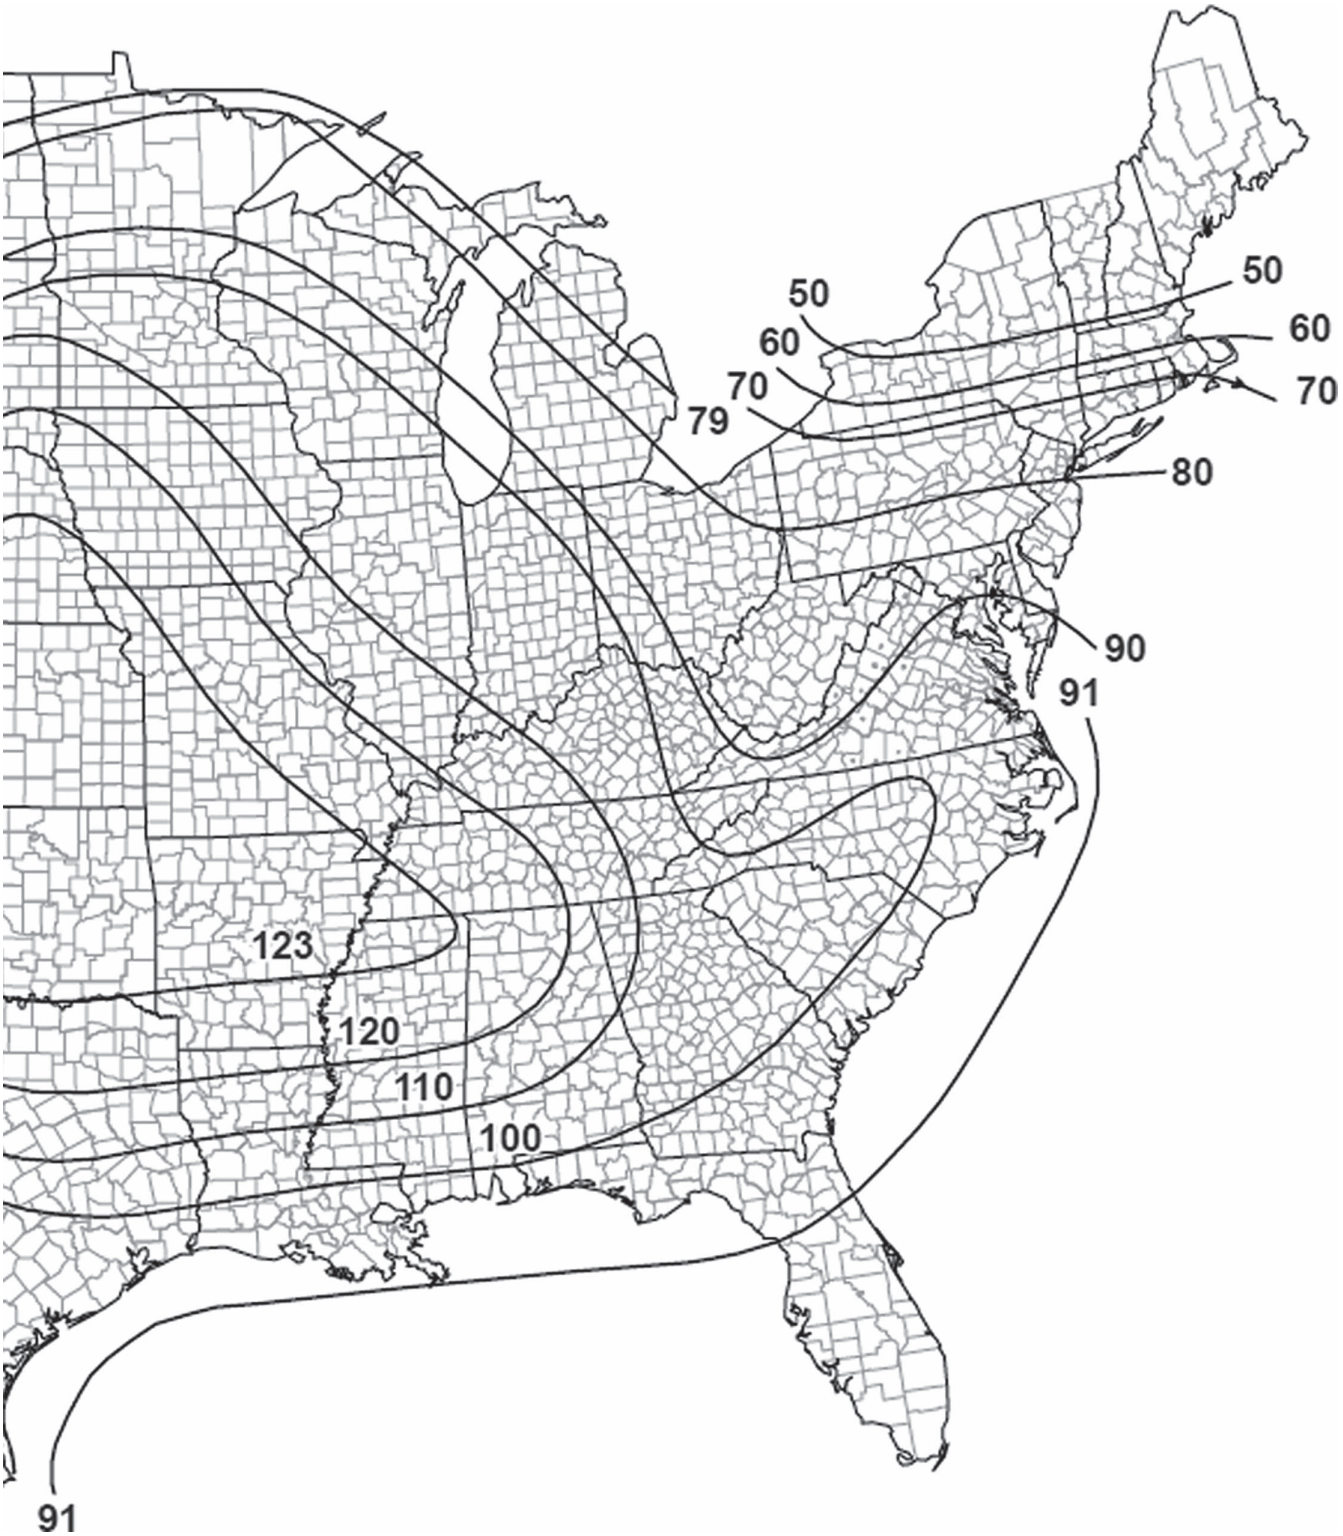
G.2 TORNADO SPEEDS

It shall be permitted to determine the tornado speed used for design tornado loads on buildings and other structures from Figures 32.A2-1 through G.2-4 as follows:

1. For 10,000-year MRI, use Figures G.2-1A through G.2-1H.
2. For 100,000-year MRI, use Figures G.2-2A through G.2-2H.
3. For 1,000,000-year MRI, use Figures G.2-3A through G.2-3H.
4. For 10,000,000-year MRI, use Figures G.2-4A through G.2-4H.

Alternatively, it shall be permitted to use the tornado speed from the ASCE Tornado Design Geodatabase. The ASCE Tornado Design Geodatabase is available at the ASCE 7 Hazard Tool (https://asce7hazardtool.online/), or approved equivalent.

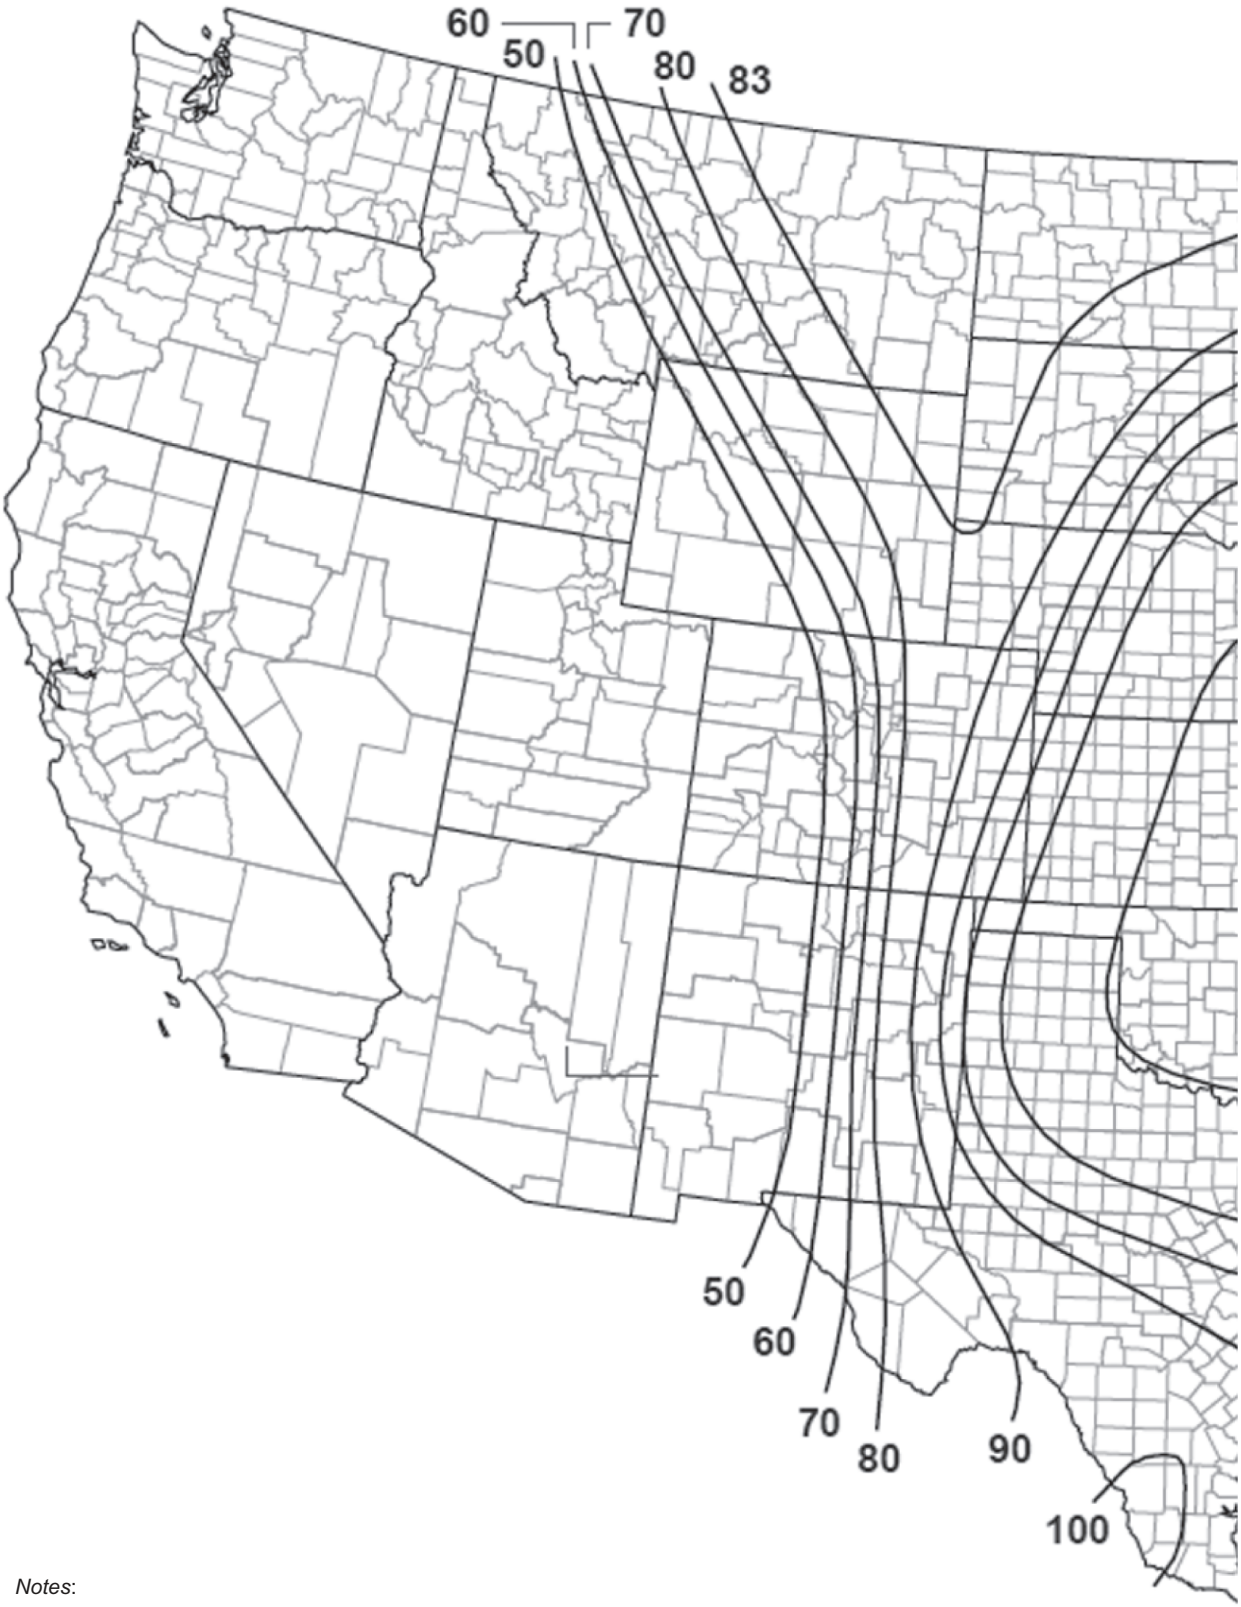
@seismicisolation
@seismicisolation



Notes:

1. Values are 3 s gust speeds in mi/h at 33 ft (10 m) above ground.
2. To convert tornado speeds from mi/h to m/s, multiply mapped values by 0.447.
3. Linear interpolation is permitted between contours. Point values (where shown) are provided to aid with interpolation.

Figure G.2-1A. Tornado speeds for 10,000-year MRI for effective plan area of 1 ft^2 (0.1 m^2).

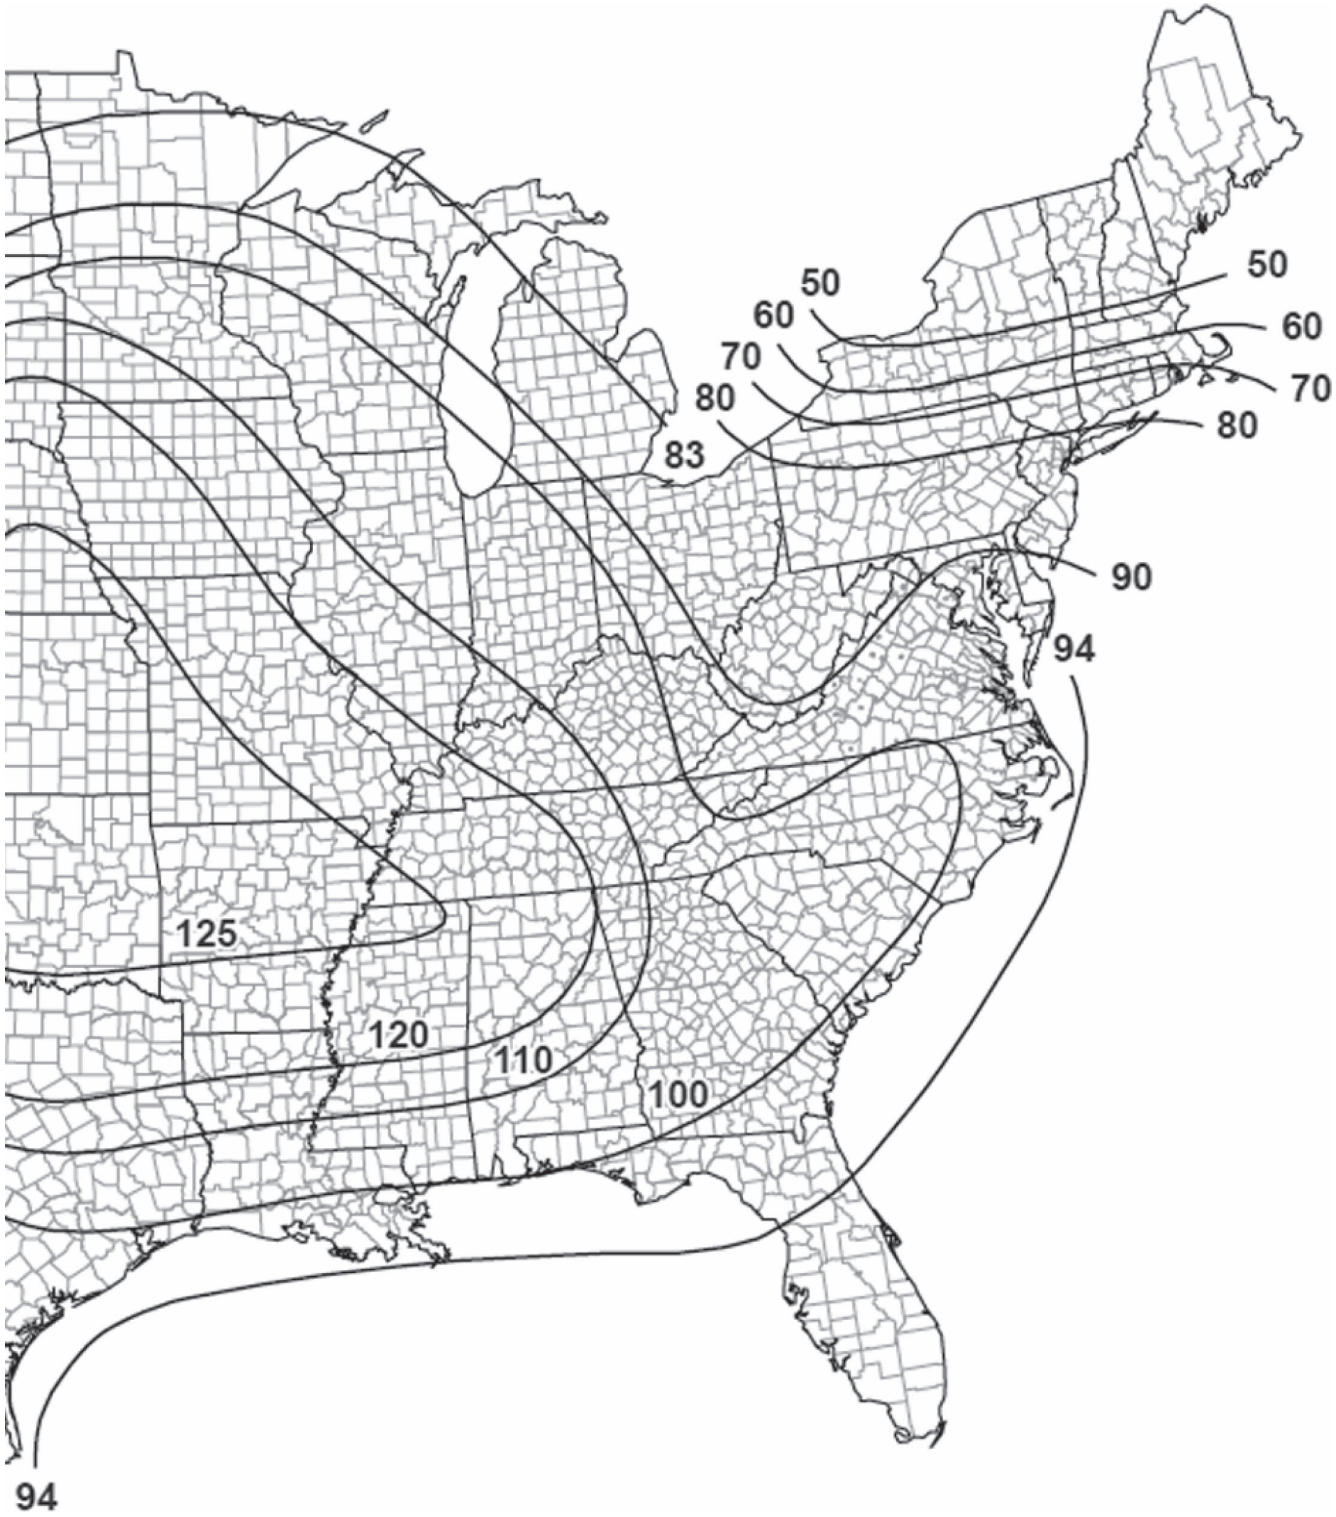


@seismicisolation

4. Islands, coastal areas, and land boundaries outside the last contour shall use the last tornado speed contour.
5. Tornado speeds correspond to approximately a 0.5% probability of exceedance in 50 years (annual exceedance probability = 0.0001, MRI = 10,000 years).
6. Location-specific tornado speed is permitted to be determined using the ASCE Tornado Design Geodatabase, available at the ASCE 7 Hazard Tool (https://asce7hazardtool.online), or approved equivalent.

Figure G.2-1A (*Continued*). Tornado speeds for 10,000-year MRI for effective plan area of 1 ft^2 (0.1 m^2).

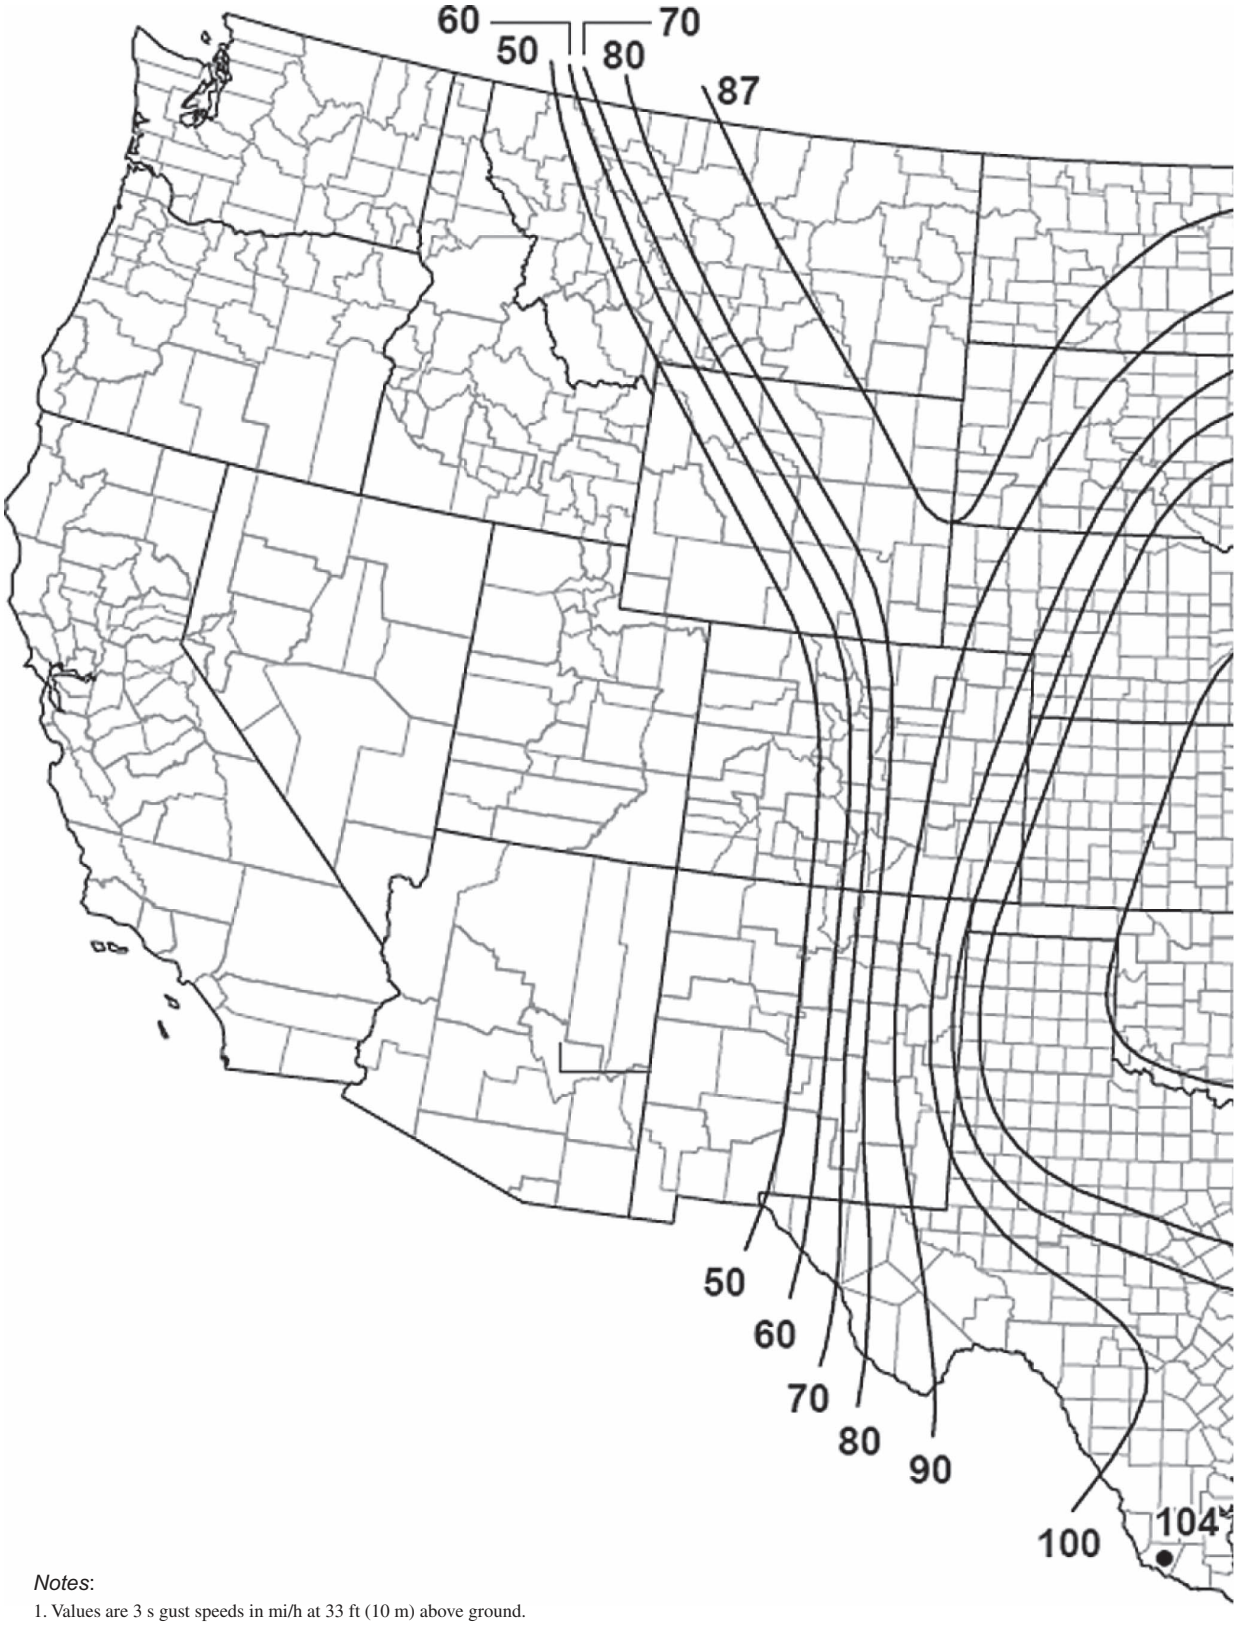
@seismicisolation



Notes:

1. Values are 3 s gust speeds in mi/h at 33 ft (10 m) above ground.
2. To convert tornado speeds from mi/h to m/s, multiply mapped values by 0.447.
3. Linear interpolation is permitted between contours. Point values (where shown) are provided to aid with interpolation.

Figure G.2-1B. Tornado speeds for 10,000-year MRI for effective plan area of 2,000 ft^2 (186 m^2).

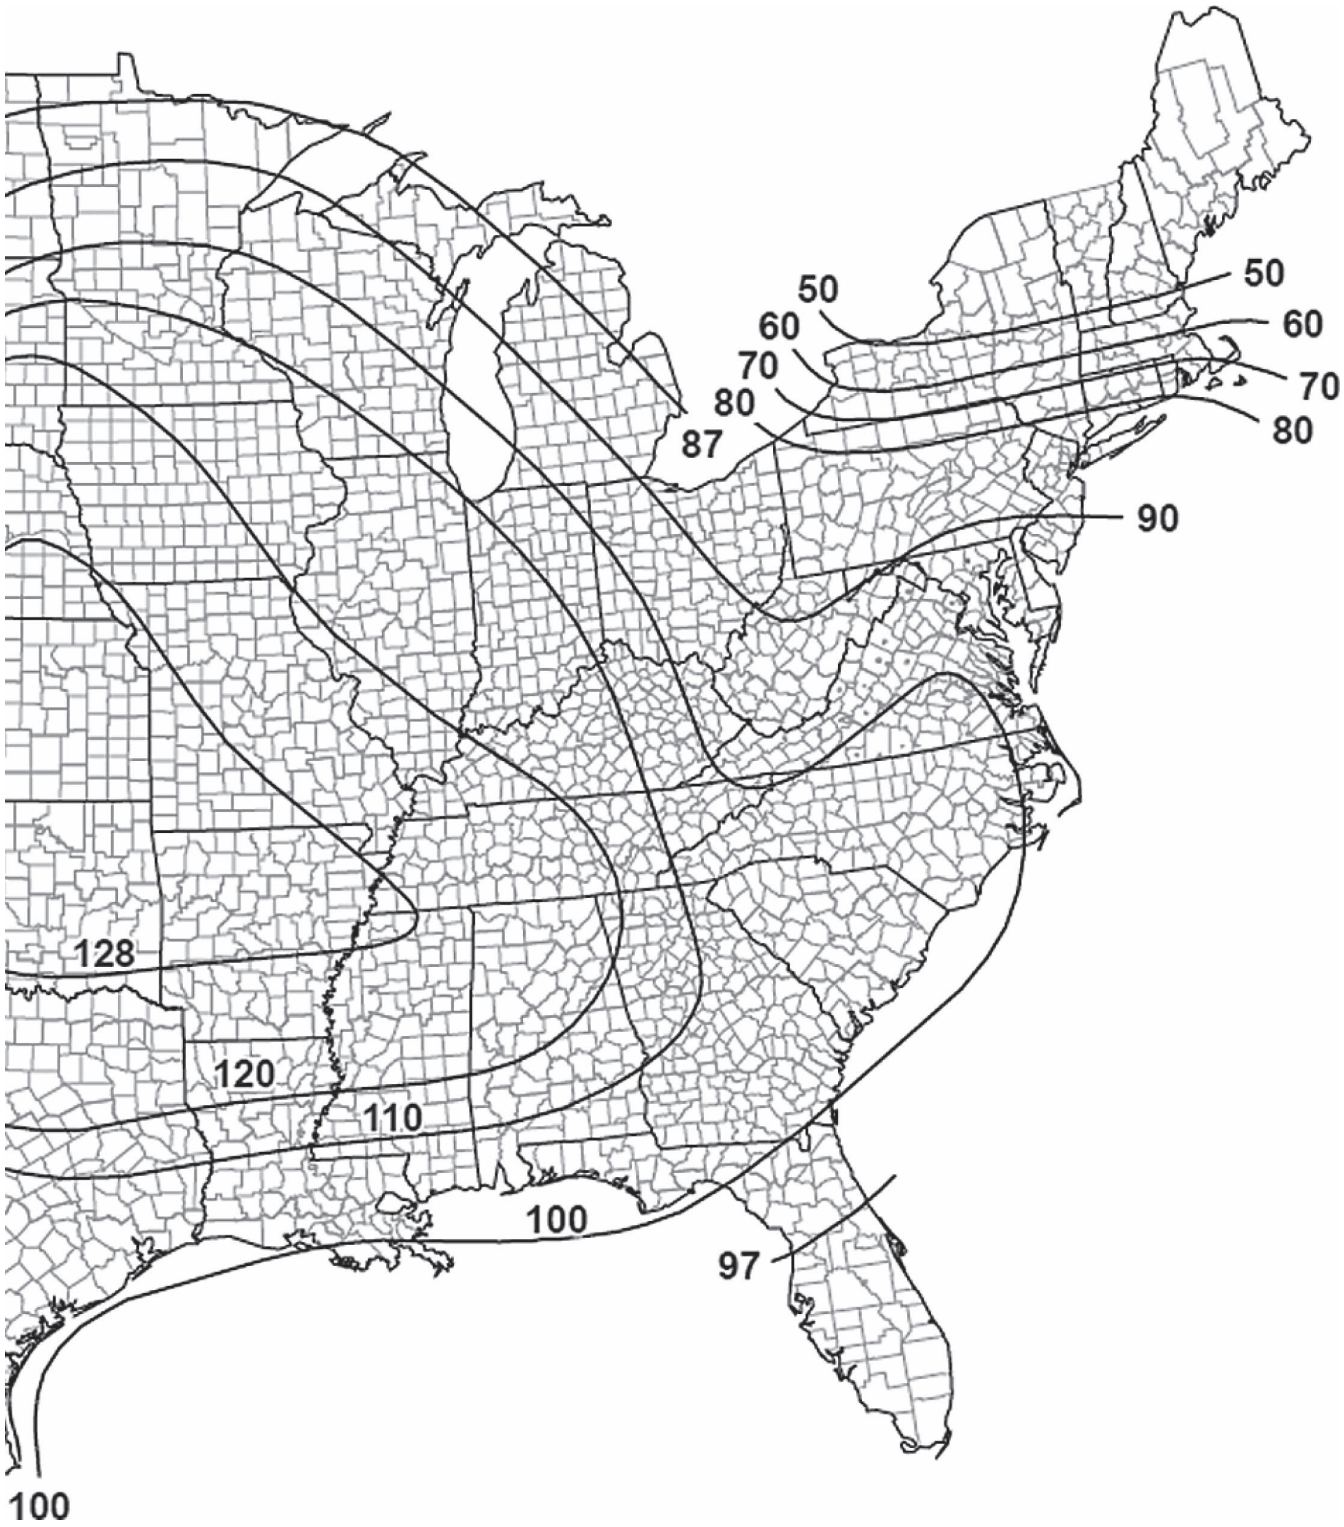


@seismicisolation

4. Islands, coastal areas, and land boundaries outside the last contour shall use the last tornado speed contour.
5. Tornado speeds correspond to approximately a 0.5% probability of exceedance in 50 years (annual exceedance probability = 0.0001, MRI = 10,000 years).
6. Location-specific tornado speed is permitted to be determined using the ASCE Tornado Design Geodatabase, available at the ASCE 7 Hazard Tool (https://asce7hazardtool.online), or approved equivalent.

Figure G.2-1B (*Continued*). Tornado speeds for 10,000-year MRI for effective plan area of 2,000 ft^2 (186 m^2).

@seismicisolation



Notes:

1. Values are 3 s gust speeds in mi/h at 33 ft (10 m) above ground.
2. To convert tornado speeds from mi/h to m/s, multiply mapped values by 0.447.
3. Linear interpolation is permitted between contours. Point values (where shown) are provided to aid with interpolation.

COMMENTARY TO STANDARD ASCE/SEI 7-22

This commentary is not part of the ASCE standard *Minimum Design Loads and Associated Criteria for Buildings and Other Structures*. It is included for information purposes.

The commentary consists of explanatory and supplementary materials designed to assist local buildings code committees and regulatory authorities in applying the recommented requirements. In some cases, it will be necessary to adjust specific values in the standard to local condidtions. In others, a considerable amount of detailed information is needed to put the provisions into effect. This commentary provides a place for supplying material that can be used in these situations and is intended to created a better understanding of the recommended requirements through brief explanations of the reasoning employed in arriving at them.

The setions of the commentary are numbered to correspond to the sections of the provisions to which they refer. Because it is not necessary to have supplementary material for every section in the standard, there are gaps in numbering in the commentary.

CHAPTER C1
GENERAL

C1.1 SCOPE

The minimum design loads, hazard levels, associated criteria, and intended performance goals contained in this standard are derived from research and observed performance of buildings, other structures, and their nonstructural components under the effects of loads. These parameters vary depending on the relative importance of the building, other structure, or nonstructural component. The loads provided in this standard include loads from both normal operations and rare hazard events. All loads and associated criteria are prescribed to achieve an intended performance, which is defined by a reliability index or limit state exceedance probability or preservation of function during a specified hazard event.

Loads and load combinations are set forth in this document with the intent that they be used together. If one were to use loads from some other source with the load combinations set forth herein or vice versa, the reliability of the resulting design may be affected.

With the 2016 edition of the standard, the title was modified to include the words "and Associated Criteria" to acknowledge what has been in this standard for many editions. For example, earthquake loads contained herein are developed for structures that possess certain qualities of ductility and postelastic energy dissipation capability. For this reason, provisions for design, detailing, and construction are provided in Chapters 11 through 22. In some cases, these provisions modify or add to provisions contained in design specifications. However, this standard only adds associated criteria when the modification is needed to achieve the intended structural performance when subjected to the loads specified herein.

Compliance with this standard is a sufficient condition for demonstrating that changes to an existing structure would meet current standards for safety. However, existing structures were designed and built to the codes and standards in effect at the time of their construction. Those codes and standards may not be consistent with the provisions of this standard. There are evolving philosophies, methodologies, standards, and codes for making decisions concerning the proper levels for safety of new parts, modified parts, existing parts, and the existing or modified structure as a whole. Model building codes such as the *International Existing Building Code* (ICC 2021) can be used as a resource for levels of safety, evaluation, strengthening, and repair requirements for existing structures. This standard does not provide overarching direction whether existing structures undergoing alteration, additions, or repairs should comply with the loads set forth in this standard or some reduced version of those loads. There are specific provisions related to existing buildings, such as Section 7.12 on snow loads on existing roofs. There are other documents, like ASCE 41 (2017), *Seismic Evaluation and Retrofit of Existing Buildings*, or ACI 562 (2019b), *Code Requirements for Assessment, Repair, and Rehabilitation of Existing Concrete Structures and Commentary*, which may contain provisions for specific hazards or construction materials.

C1.3 BASIC REQUIREMENTS

C1.3.1 Strength and Stiffness Buildings and other structures must satisfy strength limit states in which members and components are proportioned to safely carry the design loads specified in this standard to resist buckling, yielding, fracture, and other unacceptable performance. This requirement applies not only to structural components but also to nonstructural elements, the failure of which could pose a substantial safety or other risk. Chapters 30 and 32 of this standard specify wind and tornado loads, respectively, that must be considered in the design of cladding. Chapter 13 of this standard specifies earthquake loads and deformations that must be considered in the design of nonstructural components and systems designated in that chapter.

Although strength is a primary concern of this section, strength cannot be considered independent of stiffness. In addition to considerations of serviceability, for which stiffness is a primary consideration, structures must have adequate stiffness to ensure stability. In addition, the magnitude of load imposed on a structure for some loading conditions, including earthquake, wind, and ponding, is a direct function of the structure's stiffness.

Another important consideration related to stiffness is damage to nonstructural components resulting from structural deformations. Acceptable performance of nonstructural components requires that either the structural stiffness is sufficient to prevent excessive deformations, or that the components can accommodate the anticipated deformations.

Standards produced under consensus procedures and intended for use in connection with building code requirements contain recommendations for resistance factors for use with the strength design procedures of Section 1.3.1.1 or allowable stresses (or safety factors) for the allowable stress design procedures of Section 1.3.1.2. The resistances contained in any such standards have been prepared using procedures compatible with those used to form the load combinations contained in Sections 2.3 and 2.4. When used together, these load combinations and the companion resistances are intended to provide reliabilities approximately similar to those indicated in Tables 1.3-1, 1.3-2, and 1.3-3. Some standards known to have been prepared in this manner include the following:

ACI 318. *Building Code Requirements for Structural Concrete*. American Concrete Institute.

AISC 341. *Seismic Provisions for Structural Steel Buildings*. American Institute of Steel Construction.

@seismicisolation

AISC 360. *Specification for Structural Steel Buildings*. American Institute of Steel Construction.

AISI S100. *North American Specification for the Design of Cold-Formed Steel Structural Members*. American Iron and Steel Institute.

AWC NDS. *National Design Specification for Wood Construction*. American Wood Council.

AWC SDPWS. *Special Design Provisions for Wind and Seismic*. American Wood Council.

SEI/ASCE 8. *Specification for the Design of Cold-Formed Stainless Steel Structural Members*. ASCE.

Specification for Aluminum Structures. Aluminum Association.

TMS 402. *Building Code Requirements for Masonry Structures*. The Masonry Society.

TMS 602. *Specification for Masonry Structures*. The Masonry Society.

C1.3.1.3 Performance-Based Procedures Section 1.3.1.3 introduces alternative performance-based procedures that may be used in lieu of the procedures of Sections 1.3.1.1 and 1.3.1.2 to demonstrate that a building or other structure, or parts thereof, has sufficient strength. These procedures are intended to parallel the so-called alternative means and methods procedures that have been contained in building codes for many years. Such procedures permit the use of materials, design, and construction methods that differ from the prescriptive requirements of the building code, or in this case the standard, that can be demonstrated to provide equivalent performance. Such procedures are useful in that they permit innovation and the development of new approaches before the building codes and standards have an opportunity to provide for these new approaches. In addition, these procedures permit the use of alternative methods for certain special structures, which may not be covered by code but by means of their occupancy, use, or other features, can provide acceptable performance without compliance with the prescriptive requirements.

The procedures in Section 1.3.1.3 are intended to apply to all hazards specified in the standard. Some chapters of the standard have specific provisions for performance-based design for that specific load or environmental hazard while others do not. The lack of performance-based design provisions within a chapter should not be taken as a prohibition on the use of performance-based procedures for that specific load or environmental hazard.

The reliability of a proposed design does not need to be evaluated when the standard's design procedures in Sections 1.3.1.1 and 1.3.1.2 are applied. However, when performance-based procedures are used, the reliability achieved for the proposed design should be consistent with the target reliabilities stipulated in Section 1.3.1.3.

Alternative design methods have a range of implementation levels. Such methods are addressed in standards or best practice guidelines that address performance-based design goals and methodologies that incorporate the fundamental basis of reliability analysis. A minimum level of alternative design would involve standard design procedures, with analyses based on the requirements of Section 1.3.1.3. For example, a building that exceeds the code limits for building height could be designed with applicable codes and standards, and member demand and capacities would be checked to determine their adequacy for the design loads and conditions. For seismic design, the provisions of the ASCE 41 standard and of the *Guidelines for Performance-Based Seismic Design of Tall Buildings* (PEER 2010) were either calibrated by structural performance level or were demonstrated in comparison with prescriptive design methods to provide reliabilities equal to or better than those given in Table 1.3-2.

Flood load factors in ASCE 7 may not achieve the reliability targets of Table 1.3-1. For structures in the 100-year coastal flood zone, the load factor of 2.0 was based on a beta value of 2.5 (Mehta et al. 1998) rather than 3.0. For structures not in the coastal zone, the load factor of 1.0 reflects the prescriptive minimum 100-year flood elevation for stillwater flooding; thus, this flood has a 1% annual chance of being exceeded, which is essentially a beta of 1.3. For Risk Category III and IV structures, no reliability analysis has been performed. For storm events of greater return period, the flood hazard expands both in spatial extent and in depth. For those structures and components of structures that were not subject to the prescriptive flood design requirements, any design resistance depends on that imparted from design for other hazards.

Extraordinary events arise from service or environmental conditions that are not covered in the remaining chapters of ASCE 7. Such events are characterized by a low probability of occurrence and relatively short duration. While the occurrence of any of these events may cause damage ranging from local failure to incipient collapse, their occurrence is difficult or impossible to characterize statistically from current knowledge and data. Designing for low-probability, high-consequence events requires an approach that addresses the unique risks posed by such events and recognizes that performance-based approaches often will be used for dealing with them. Accordingly, Table 1.3-5 and Section 2.5 are based on a *scenario* approach, in which the structural design criteria are based on *conditional* reliability targets, given the occurrence of extraordinary event scenarios identified by the design team and approved by the Authority Having Jurisdiction to achieve structural performance that is essential for public safety. The target reliabilities in Table 1.3-5 are consistent with the discussion of conditional reliabilities in Section C2.5 but have been expanded to cover the four risk categories in Table 1.5-1. The reader is directed to Section C2.5 for a detailed discussion of these reliability considerations.

The alternative procedures of Section 1.3.1.3 may be used to demonstrate adequacy for one or more design loads, while the standard procedures of Sections 1.3.1.1 and 1.3.1.2 are used to demonstrate adequacy for other design loads. For example, it is relatively common to use the alternative procedures to demonstrate adequate earthquake, fire, or blast resistance, while the standard prescriptive procedures of Sections 1.3.1.1 and 1.3.1.2 are used for all other loading considerations.

The alternative procedures of Section 1.3.1.3 are intended to be used in the design of individual projects, rather than as the basis for broad qualification of new structural systems, products, or components. Procedures for such qualification are beyond the scope of this standard, because the limited number of test data required in Section 1.3.1.3.2 are not appropriate for the application of new materials in a structural system or the development of prefabricated structural assemblies intended for general widespread use in structural systems. A more robust level of testing is needed for new materials or structural assemblies for general use.

Section 1.3.1.3 requires demonstration that a design has adequate strength to provide an equivalent or lower probability of failure under load than that adopted as the basis for the prescriptive requirements of this standard for buildings and structures of comparable risk category. Tables 1.3-1, 1.3-2, and 1.3-3 summarize performance goals, expressed in terms of target reliabilities, associated with protection against structural failure that approximate those notionally intended to be achieved using the design procedures of Section 2.3. The target reliability

@seismicisolation

indexes are provided for a 50-year reference period, and the probabilities of failure are annual probabilities. Annualized probabilities can be applied to limit states where the loads and member resistance do not vary over the reference period. If a member is subject to degradation, such as corrosion, then degradation effects over the service period should be considered through a time-varying or stochastic process as part of the reliability analysis.

The target reliabilities have been developed and vetted by a number of consensus groups over a period of more than 30 years and have been confirmed through professional practice in AISC 360 (AISC 2022b), ACI 318 (ACI 2019a), and other standards and documents. The target reliabilities for Risk Category II in Table 1.3-1 are based on probabilistic analyses of structural member performance for strength design procedures and are documented in Ellingwood et al. (1980, 1982) and Galambos et al. (1982). The reliabilities are consistent with those adopted by the NBCC M-32A (2010), TC 250 (CEN 2002b), and ISO 2394 (1998). Structural members and connections designed using typical specifications for engineering materials (steel, reinforced concrete, masonry, and timber) were analyzed to determine their reliability for common limit states, such as yielding in tension members, formation of plastic hinges in compact laterally supported beams, or column buckling and connection fracture for a nominal service period of 50 years. The reliabilities were initially determined for load combinations involving dead, live, wind, snow, and earthquake loads. The target reliabilities listed in Table 1.3-1 are based on strength criteria for structural members. The target reliabilities listed in Table 1.3-2 for strength and deflection limit states are based on strength and deflection criteria for system response to earthquakes where inelastic behavior is assumed. The target reliabilities for Risk Categories I, III, and IV were determined by reviewing the intended performance of structural members and systems as well as target reliabilities specified by other codes and standards for similar performance criteria.

Seismic design practice has evolved in the last three decades from the original reliability basis mentioned previously. The target reliabilities in Table 1.3-2 for earthquake-resistant structural system design are defined for the response of the structural system as described in NIST (2012), which was prepared by NEHRP Consultants Joint Venture. For Risk Category I and II structures, that is, $I_e = 1.0$, acceptable Life Safety risk is defined by an "absolute" collapse probability of 1% in 50 years and a "conditional" probability of 10% given risk-targeted maximum considered earthquake (MCE_R) ground motions. The conditional probability of 10% is based on FEMA P-695 (2009) methodology. The absolute probability of 1% in 50 years and the conditional probability of 10% given MCE_R ground motions were used by the US Geological Survey to develop the probabilistic MCE_R ground motions of ASCE/SEI 7-10. The conditional probabilities of 5% (Risk Category III structures) and 2.5% (Risk Category IV structures) represent improved reliability anticipated for structures designed with an Importance Factor, I_e, greater than 1.0. Although not specifically stated by the ASCE/SEI 7-10 commentary, it may be presumed that Risk Categories III and IV structures have absolute collapse probability objectives that are less than 1% in 50 years (i.e., due to design using an Importance Factor of $I_e > 1.0$).

Engineers may need load criteria for strength design that are consistent with the requirements in this standard for situations that are not covered explicitly within this standard. They may also need to consider load criteria for special situations, as required by the client in performance-based engineering applications, in accordance with Section 1.3.1.3. In addition, groups writing standards and specifications for strength design of structural systems and elements may need to develop resistance factors that, when used with the load requirements in this standard, permit the stipulated reliability to be achieved. Such load criteria should be developed using an accepted procedure, such as that provided in Section 2.3.6, to ensure that the resulting factored design loads and load combinations are consistent with target reliabilities (or levels of performance), the common load criteria in Section 2.3.2, and existing standards and specifications governing strength design for common construction materials. Peer-reviewed statistical data for loads in this standard, adopted from Ellingwood et al. (1980, 1982) and Galambos et al. (1982), are provided in Table C1.3-1. The statistics provided are the ratio of the mean, X_m, to nominal, X_n, values of the load and the coefficient of variation (COV) of a cumulative distribution function (CDF) fitted to the 90th percentile and above of the probability distribution of the load. The parameters for S (snow) are based on data for the northeastern quadrant of the United States. The environmental hazards in this Standard do not reflect potential effects of climate variability and climate change.

Table C1.3-1. Load Distributions and Parameters.

Load	X_m/X_n	V_x	Cumulative Distribution Function (CDF)
Dead, D	1.05	0.10	Normal
Live, L	1.00	0.25	Type I
Wind, W	Site-dependent		Type I
Snow, S	Site-dependent	0.26	Generalized Extreme Value
Earthquake, E	Site-dependent		Type II

The reliability of structural members can be determined through a reliability analysis, such as a Monte Carlo analysis with random variables assigned probability distributions with mean and COV values based on statistical data. Reliability analyses can also be conducted using a nonparametric hazard curve based on data. Figure C1.3-1 provides an example of the design equation, limit state equations, and statistical variables for a compact steel flexural member designed for dead plus live load. The statistics used in this example are typical (compare Table C1.3-1). The user should determine the appropriate probabilistic models for his or her design situation.

Figure C1.3-1 presents an illustration of how the reliability index, β, is determined for the common case of a compact steel beam with full lateral support, in which the limit state is the formation of the first plastic hinge. The reliability depends on the ratio of nominal live to dead load in the limit state equation. For $L_n/D_n = 2.0$ (a typical value), the probability of failure (50-year basis) is 0.00298. The corresponding reliability index $\beta = \Phi^{-1}(1 - P_f) = 2.75$ (50-year basis), and $P_f = 6 \times 10^{-5}$ (annual basis). These reliabilities can be compared to the reliability targets in Table 1.3-1. The variation in β with L_n/D_n is very small; unlike in allowable stress design (ASD), the dead and live load factors of 1.2 and 1.6 were selected so as to properly reflect the differences in variability between dead and live load.

The system reliabilities for earthquake are different from those for other environmental hazards because the design philosophy of the standard is to prevent system collapse in the risk-targeted maximum considered earthquake (MCE_R) shaking. The R, C_d, and Ω_0 coefficients specified in Chapter 12 for seismic loading, together with the systems detailing requirements specified in the referenced standards, are intended to ensure minimum acceptable

@seismicisolation

Design Equation

$$0.9R_n = 1.2D_n + 1.6L_n$$

Limit State Equation *G*(*X*)

$$G(R, D, L) = R - D - L$$

$$G(X) = \left(\left[1.2 + 1.6\left(\frac{L_n}{D_n} \right) \right] / 0.9 \right) X_1 - X_2 - \left(\frac{L_n}{D_n} \right) X_3$$

where

R = Strength random variable, and R_n = Nominal strength;

D = Dead load random variable, and D_n = Nominal dead load;

L = Live load random variable, and L_n = Nominal live load;

$X_1 = R/R_n$, $X_2 = D/D_n$, $X_3 = L/L_n$; and

Typical range of L/D_n is 0.5 to 4.0.

X_3	1.00	0.25	Type I

Figure C1.3-1. Equations and statistics of load and resistance parameters for a Monte Carlo analysis to determine achieved reliability.

probabilities of structural collapse, given the occurrence of MCE_R ground shaking. As discussed in Section C11.4, for typical structures (Risk Categories I and II), the conditional probability of collapse is assumed to be 10%, given the occurrence of the MCE_R. This assumption is based on significant research documented in FEMA P-695 (2009). The additional collapse goals of 5% for Risk Category III and 2.5% for Risk Category IV were arrived at by assuming that the seismic fragility (probabilistic model of system strength) is described by a lognormal distribution with a logarithmic standard deviation of 0.6 and adjusting the strength of the structure by the earthquake Importance Factors of 1.25 and 1.5, respectively. Since collapse is a function of loading (ground shaking) intensity, still lower but nonnegligible probabilities of collapse also exist at design shaking levels. The collapse risk for design earthquake shaking is approximately 2.5%, 1%, and 0.5% for Risk Categories II, III, and IV structures, respectively.

This standard also seeks to protect against local failure that does not result in global collapse but could result in injury risk to a few persons. Chapter 16 of the standard defines structural elements according to their criticality as critical, ordinary, and noncritical, where critical elements can lead to global collapse, ordinary elements to endangerment of a limited number of lives, and noncritical elements do not have safety consequences. For ordinary elements in Risk Category II structures, the standard accepts a 25% probability of failure given MCE_R shaking (approximately 10% probability of failure for design earthquake shaking). Failure probabilities for ordinary elements in Risk Category III and IV structures are, respectively, 15 and 9% for MCE_R shaking and 4% and 2% for DE shaking. It is anticipated that the failure probabilities for anchorage of rigid nonstructural components attached at grade to the structure may be in the same range as the probabilities for ordinary elements. However, the uncertainties associated with the reliability for anchorage of rigid nonstructural components that are elevated within a structure are much higher than for structural elements because the methods used to characterize the strength demands on nonstructural components are more approximate than those used for overall building demands, and appropriate reliability levels have not yet been established for them. Furthermore, demands on anchorage of flexible nonstructural components and distributions are significantly more complex, especially when the points of attachment of the nonstructural components are elevated within a structure and one needs to consider both inertial effects and relative displacements. Future study should seek to evaluate nonstructural reliabilities in a rigorous manner, and if consensus can be achieved regarding the appropriate reliability levels for anchorage, to adjust the design procedure for anchorage of these components to achieve these appropriate reliabilities.

The reliabilities for tsunami loads are for the performance-based design of inundated structural elements to prevent failure from hydrodynamic loading during the Maximum Considered Tsunami (MCT). The target reliabilities given in the standard

@seismicisolation

have their basis in the analysis by Chock et al. (2016). Probabilistic limit-state reliabilities were computed for representative structural components carrying gravity and tsunami loads, using statistical information on the key hydrodynamic loading parameters and resistance models with specified tsunami load combination factors. The prescriptive design criteria for waterborne debris impacts and foundation scour are not probabilistic, and therefore these effects are not included in Table 1.3-4. Guidance for performance-based design for tsunami loads can be found in Chapter 6 and its associated commentary.

It is important to note that provision of adequate strength is not sufficient to ensure proper performance. Considerations of serviceability and structural integrity are also important. Use of the alternative procedures of Section 1.3.1.3 is not intended as an alternative to the requirements of Sections 1.3.2, 1.3.3, 1.3.4, 1.3.5, 1.3.6, or 1.4 of this standard.

The requirements of this standard and its companion referenced standards are intended to provide protection against structural failure. They are also intended to provide property and economic protection for small events, to the extent practical, as well as improve the probability that critical facilities will be functional after severe storms, earthquakes, and similar events. Although these goals are an important part of the requirements of this standard, at the present time there is no documentation of the reliability intended with respect to these goals. Consequently, Tables 1.3-1 and 1.3-2 address safety considerations only.

Compliance with Section 1.3.1.3 may be demonstrated by analysis, testing, or a combination of both methods. It is important to recognize that there is uncertainty as to whether the performance objectives tabulated in Tables 1.3-1 and 1.3-2 can be achieved. There is inherent uncertainty associated with prediction of the intensity of loading that a structure will experience, the actual strength of materials incorporated in construction, the quality of construction, and the condition of the structure at the time of loading. Whether testing, analysis, or a combination of these is used, provision should be made to account for these uncertainties and to ensure that the probability of poor performance is acceptably low. See Ellingwood et al. (1982) and Galambos et al. (1982) for estimates of such uncertainties.

Rigorous methods of reliability analysis can be used to demonstrate that the reliability of a design achieves the targets indicated in Tables 1.3-1 and 1.3-2; a simple illustration of such a method is provided in Figure C1.3-1. While such analyses would certainly constitute an acceptable approach to satisfy the requirements of Section 1.3.1.3, these may not be the only acceptable approaches. Consensus bodies or other standards developing organizations may develop guideline documents that provide alternative performance-based design methods or alternate prescriptive procedures that meet or exceed the reliabilities stated in this section.

Since most building officials and other Authorities Having Jurisdiction do not have the expertise necessary to judge the adequacy of designs justified using the Section 1.3.1.3 procedures, independent peer review is an essential part of this process. Peer review can help reduce the potential that the design professional of record will overlook or misinterpret one or more potential behaviors that could result in poor performance. Peer review can also help establish that an appropriate standard of care was adhered to during the design. For peer review to be effective, the reviewers must have the appropriate expertise and understanding of the types of structures, loading, analysis methods, and testing used in the procedures.

The target reliabilities listed in Table 1.3-1 for members and connections and those in Tables 1.3-2 and 1.3-3 for structural systems are included in this standard specifically for application to performance-based procedures for individual projects that are peer reviewed by experts in the field. For several reasons, these target reliabilities are not intended to be compared to reliability indexes developed by material specification groups for general structural applications. For example, reliability indexes for some materials are based on testing of small coupons of the material, supplemented by factors to account for scaling up to structural-sized elements, whereas other materials test full-sized structural members as the foundation for this analysis. Additionally, some reliability analyses use default lognormal data distribution assumptions, and others use distributional forms applicable to the material and to each load combination of interest.

C1.3.1.3.2 Project-Specific Performance Capability Testing
Laboratory testing of materials and components constructed from those materials is an essential part of the process of validating the performance of structures and nonstructural components under load. Design resistances specified in the industry standards used with the strength procedures of Section 1.3.1.1 and the allowable stress procedures of Section 1.3.1.2 are based on extensive laboratory testing and many years of experience with the performance of real structures designed using these standards. Similarly, analytical modeling techniques commonly used by engineers to predict the behavior of these systems have been benchmarked and validated against laboratory testing. Similar benchmarking of resistance, component performance, and analytical models is essential when performance-based procedures are used. Where systems and components that are within the scope of the industry standards are used in a design, analytical modeling of these systems and components and their resistances should be conducted in accordance with these standards and industry practice, unless new data and testing suggest that other assumptions are more appropriate. Where new systems, components, or materials are to be used, laboratory testing must be performed to indicate appropriate modeling assumptions and resistances.

No single protocol is appropriate for use in laboratory testing of structural and nonstructural components. The appropriate number and types of tests that should be performed depend on the type of loading the component will be subjected to, the complexity of the component's behavior, the failure modes it may exhibit, the consequences of this failure, and the variability associated with the behavior. Resistances should be selected to provide an acceptably low probability of unacceptable performance. Commentary to Chapter 2 provides guidance on the calculation of load and resistance factors that may be used for this purpose, when LRFD procedures are used.

Regardless of the means used to demonstrate acceptable performance, testing should be sufficient to provide an understanding of the probable mean value and variability of resistance or component performance. For materials or components that exhibit significant variability in behavior as a result of either workmanship, material variation, or brittle modes of behavior, a very large number of tests may be required to properly characterize both the mean values and dispersion. It is seldom possible to conduct such a large number of tests as part of an individual project. Therefore, for reasons of practicality, this standard permits a small number of tests, with the number based on the observed variability. Users are cautioned to conduct tests on material that is representative of that expected to be used in the specific project and to check that all significant sources of variability are included in the test samples. When high variability is observed in these test data, the minimum requirement of six tests is not adequate to establish either the true mean or the

@seismicisolation

variability with confidence, and appropriate caution should be used when developing component resistance or performance measures based on this limited testing. This is a primary reason why the procedures of this section are limited to use on the specific projects being analyzed (i.e., they are not "portable" to similar projects) and that data from these tests are not intended as a means of obtaining prequalification of new systems, materials, or components for broad application.

Some industries and industry standards have adopted standard protocols and procedures for qualification testing. For example, AISC 341 (AISC 2022a), Chapter K, specifies the required testing for qualification of connections used in certain steel seismic force-resisting systems. The wood structural panel industry has generally embraced the testing protocols developed by the Consortium of Universities for Research in Earthquake Engineering project (Krawinkler et al. 2002). When a material, component, or system is similar to those for which such an industry standard exists, the industry standard should be used, unless it can be demonstrated to the satisfaction of peer review and the Authority Having Jurisdiction that more appropriate results will be attained by using alternative procedures and protocols.

When data from Section 1.3.1.3.2 testing are used to characterize a variable in the reliability analysis, sample sizes shall be sufficient to define the mean and coefficient of variation of the test results within specific confidence bounds determined by the significance of that variable in the reliability analysis. While most testing being conducted in accordance with Section 1.3.1.3.2 will be used primarily to confirm or supplement engineering analyses, it is possible that test data will also be used to characterize one of the random variables that are part of the reliability analysis. Because each variable in the reliability analysis will influence the final computed reliability index, each test-based variable must be subjected to a reasonable amount of statistical rigor. For very small sample sizes, it is not possible to define the mean or the standard deviation precisely. However, there are well-established methods to compute confidence bounds on those parameters. For example, a conservative estimate of the mean value might be the lower 75% confidence bound.

C1.3.2 Serviceability In addition to strength limit states, buildings and other structures must also satisfy serviceability limit states that define functional performance and behavior under loads normally experienced during the lifetime of the structure or during a time defined specifically for a project or a particular limit state. Serviceability limit states include such items as deflection and vibration. In the United States, strength limit states have traditionally been specified in building codes because they control the safety of the structure. Serviceability limit states, however, are usually noncatastrophic, define a level of quality of the structure or element, and are a matter of judgment as to their application. Serviceability limit states involve the perceptions and expectations of the owner or users and are a contractual matter between the owner or users and the designer and builder. It is for these reasons, and because the benefits are often subjective and difficult to define or quantify, that serviceability limit states for the most part are not included in the model US building codes, with several notable exceptions, such as member deflection limits. In some cases, material design standards provide serviceability limit states for structural elements composed of their material.

The fact that serviceability limit states are usually not codified should not diminish their importance. Exceeding a serviceability limit state in a building or other structure usually means that its function is disrupted or impaired because of local minor damage or deterioration or because of occupant discomfort or annoyance. Therefore, this section states that serviceability limit states and the service loads associated with those limit states should be defined in the project design criteria, which would often be developed in consultation with the owner of the building or other structure. Appendix C and its commentary provide guidance to the designer on developing serviceability design criteria.

Service loads can vary significantly from the design loads specified in this standard. Often the service loads are dependent on the specific serviceability limit state being investigated. For example, beam deflection for a stiffness serviceability limit state has typically been evaluated using the live load as specified in this standard, without a load factor applied to it. While the live load used for evaluating floor vibration caused by footfall has commonly been taken as an estimated average of the actual live load present, often significantly less than the design live load is specified in this standard.

C1.3.3 Functionality Structures in Risk Category IV are intended to have some measure of protection against damage to the structure and to designated nonstructural systems that would preclude the facility from resuming its intended function following the design environmental hazard. For example, in Chapter 13 of the standard, nonstructural systems assigned to Risk Category IV must be tested or verified by analysis to be rugged enough to retain their pre-earthquake function following the design earthquake. There are additional requirements in the seismic chapters (Chapters 11 through 23) to limit structural damage and drift to preserve function of the structure. Because the provisions of this standard require that structures and nonstructural components be designed to remain essentially elastic under most other environmental hazards, preservation of function is generally provided.

When a performance-based design is elected over the prescriptive design procedures in the standard, the registered design professional should confirm that the structure has sufficient strength and stiffness to not incur damage during the design environmental hazard event that would prevent the facility from resuming its intended function, or in some cases or hazards, continue functioning during the design hazard.

Because the nature of function preservation is very broad and encompasses many different structural components and systems subjected to various hazards, there are not specific reliability targets. For that reason, the terms *reasonable probability* and *adequate structural strength* as applied to structural systems are used to indicate that the application of Section 1.1.3 is not an absolute target value. What constitutes reasonable probability depends on many factors, including the recognition that the fragilities of structural systems to ensure function are not well established and should be agreed on by the user, the client, and if applicable, the Authority Having Jurisdiction and the peer reviewers.

The designated nonstructural systems should be composed of components that have adequate strength, stiffness, and ruggedness and are adequately connected or restrained to the structure so that they do not incur damage sufficient to prohibit the function of the system within a specified period of time as the facility is brought back online. This functionality can be demonstrated through analysis or through physical testing of the nonstructural system or components.

Designated nonstructural systems may vary between structures based on the function of the facility. However, systems that are essential to Life Safety are commonly accepted as needed function preservation. Such systems may include fire detection and suppression systems, emergency exit lighting, and systems

@seismicisolation
@seismicisolation

that contain explosive, toxic, or highly toxic materials. The specific systems and components that should be considered part of the designated nonstructural system should be determined by the user and may require approval by the Authority Having Jurisdiction and, if part of the design, the peer reviewers.

The requirements of this section are not to preclude damage to the structural elements or nonstructural components. In fact, there might be considerable damage to nonessential nonstructural systems and some indications of inelastic deformation of the structure. There should be no structural damage that would indicate the structure is unsafe to support the loads with reliability similar to that required to support it during normal operation. There should be no damage to the nonstructural components that prevents function, such as blocked egress routes. Designated nonstructural systems may have cosmetic damage, but the components can function as they did before the hazard.

The statement that the provisions within this standard are deemed to comply with this section means that through following the prescriptive provisions contained herein, the design professional should be able to provide the intended function preservation performance of Risk Category IV structures in a reasonable period of time consistent with the current state of the practice. In some chapters of this standard, there are other terms that refer to essentially the same components as "Designated Nonstructural System." "Designated Seismic System" in Chapter 13 and "Critical Equipment and Systems" in Chapter 6 are two examples. In those cases, the chapter-specific hazard terms are retained to allow the hazard-specific requirements to be implemented.

C1.3.4 Self-Straining Forces and Effects Indeterminate structures that experience dimensional changes develop self-straining forces and effects. Examples include moments in rigid frames that undergo differential foundation settlements, pretensioning or posttensioning forces as well as any relaxation or loss of such forces sufficient to affect structural performance, and shear forces in bearing walls that support concrete slabs that shrink. Unless provisions are made for self-straining forces and effects, stresses in structural elements, either alone or in combination with stresses from external loads, can be high enough to cause structural damage.

In many cases, the magnitude of self-straining forces can be anticipated by analyses of expected shrinkage, temperature fluctuations, foundation movement, and so forth. However, it is not always practical to calculate the magnitude of self-straining forces. Designers often specify relief joints, suitable framing systems, or other details to minimize self-straining forces and effects.

C1.3.7 Fire Resistance Where there is no applicable building code (the building code under which the structure is designed), the structural fire resistance provisions of the International Building Code (ICC 2021) should be applied. Appendix E provides performance-based design procedures for alternative means specified in Section 1.3.1.

C1.4 GENERAL STRUCTURAL INTEGRITY

Sections 1.4.1 through 1.4.4 present minimum strength criteria intended to ensure that all structures are provided with minimum interconnectivity of their elements and that a complete lateral force-resisting system is present with sufficient strength to provide stability under gravity loads and nominal lateral forces that are independent of design wind, tornado, seismic, or other anticipated loads. Conformance with these criteria provides structural integrity for normal service and minor unanticipated events that may reasonably be expected to occur throughout their lifetimes. For many structures that house large numbers of persons, or that house functions necessary to protect the public safety or occupancies that may be the subject of intentional sabotage or attack, more rigorous protection should be incorporated into designs than provided by these sections. For such structures, additional precautions can and should be taken in the design of structures to limit the effects of local collapse and to prevent or minimize progressive collapse in accordance with the procedures of Section 2.5, as charged by Section 1.4. Progressive collapse is defined as the spread of an initial local failure from element to element, resulting eventually in the collapse of an entire structure or a disproportionately large part of it.

Some authors have defined resistance to progressive collapse to be the ability of a structure to accommodate, with only local failure, the notional removal of any single structural member. Aside from the possibility of further damage that uncontrolled debris from the failed member may cause, it appears prudent to consider whether the abnormal event will fail only a single member.

Because accidents, misuse, and sabotage are normally unforeseeable events, they cannot be defined precisely. Likewise, general structural integrity is a quality that cannot be stated in simple terms. It is the purpose of Section 1.4 and this commentary to direct attention to the problem of local collapse, present guidelines for handling it that will aid the design engineer and promote consistency of treatment in all types of structures and in all construction materials. ASCE does not intend, at this time, for this standard to establish specific events to be considered during design or for this standard to provide specific design criteria to minimize the risk of progressive collapse.

Accidents, Misuse, Sabotage, and their Consequences. In addition to unintentional or willful misuse, some of the incidents that may cause local collapse (Leyendecker et al. 1976) are explosions caused by ignition of gas or industrial liquids, boiler failures, vehicle impact, impact of falling objects, effects of adjacent excavations, gross construction errors, and sabotage. In general, such abnormal events would not be a part of normal design considerations. The distinction between general collapse and limited local collapse can best be made by example, as follows.

General Collapse. The immediate deliberate demolition of an entire structure by phased explosives is an obvious instance of general collapse. Also, the failure of one column in a one-, two-, three-, or possibly even four-column structure could precipitate general collapse because the local failed column is a significant part of the total structural system at that level. Similarly, the failure of a major bearing element in the bottom story of a two- or three-story structure might cause general collapse of the whole structure. Such collapses are beyond the scope of the provisions discussed herein. There have been numerous instances of general collapse that have occurred as the result of such events as bombing, landslides, and floods.

Limited Local Collapse. An example of limited local collapse would be the containment of damage to adjacent bays and stories following the destruction of one or two neighboring columns in a multibay structure. The restriction of damage to portions of two or three stories of a higher structure following the failure of a section of bearing wall in one story is another example.

Examples of General Collapse

Ronan Point. A prominent case of local collapse that progressed to a disproportionate part of the whole building (and is thus an example of the type of failure of concern here) was the Ronan Point disaster, which brought the attention of the profession to the matter of general structural integrity in buildings. Ronan Point was a 22-story apartment building of large precast concrete

@seismicisolation

load-bearing panels in Canning Town, England. In March 1968, a gas explosion in an 18th-story apartment blew out a living room wall. The loss of the wall led to the collapse of the whole corner of the building. The apartments above the 18th story, suddenly losing support from below and being insufficiently tied and reinforced, collapsed one after the other. The falling debris ruptured successive floors and walls below the 18th story, and the failure progressed to the ground. Better continuity and ductility might have reduced the amount of damage at Ronan Point.

Another example is the failure of a one-story parking garage reported in Granstrom and Carlsson (1974). Collapse of one transverse frame under a concentration of snow led to the later progressive collapse of the whole roof, which was supported by 20 transverse frames of the same type. Similar progressive collapses are mentioned in Seltz-Petrash (1979).

Alfred P. Murrah Federal Building. On April 19, 1995, a truck containing approximately 4,000 lb (1,800 kg) of fertilizer-based explosive (ammonium nitrate/fuel oil) was parked near the sidewalk next to the nine-story reinforced concrete office building (Weidlinger 1994, Engineering News-Record 1995, Longinow 1995, Glover 1996). The side facing the blast had corner columns and four other perimeter columns. The blast shock wave disintegrated one of the 20 × 36 in. (510 × 920 mm) perimeter columns and caused brittle failures of two others. The transfer girder at the third level above these columns failed, and the upper-story floors collapsed in a progressive fashion. Approximately 70% of the building experienced dramatic collapse. One hundred sixty-eight people died, many of them as a direct result of the progressive collapse. Damage might have been less had this structure not relied on transfer girders for support of upper floors, if there had been better detailing for ductility and greater redundancy, and if there had been better resistance for uplift loads on floor slabs.

There are a number of factors that contribute to the risk of damage propagation in modern structures (Breen 1976). Among them are the following:

1. There is an apparent lack of general awareness among engineers that structural integrity against collapse is important enough to be regularly considered in design.
2. To give more flexibility in floor plans and to keep costs down, interior walls and partitions are often non-load-bearing and hence may be unable to assist in containing damage.
3. In attempting to achieve economy in structure through greater speed of erection and less construction site labor, systems may be built with minimum continuity, ties between elements, and joint rigidity.
4. Unreinforced or lightly reinforced load-bearing walls in multistory structures may also have inadequate continuity, ties, and joint rigidity.
5. In roof trusses and arches, there may not be sufficient strength to carry the extra loads or sufficient diaphragm action to maintain lateral stability of the adjacent members if one collapses.
6. In eliminating excessively large safety factors, code changes over the past several decades have reduced the large margin of safety inherent in many older structures. The use of higher-strength materials permitting more slender sections compounds the problem in that modern structures may be more flexible and sensitive to load variations and, in addition, may be more sensitive to construction errors.

Experience has demonstrated that the principle of taking precautions in design to limit the effects of local collapse is realistic and can be satisfied economically. From a public safety viewpoint, it is reasonable to expect all multistory structures to possess general structural integrity comparable to that of properly designed, conventionally framed structures (Breen 1976, Burnett 1975).

Design Alternatives. There are a number of ways to obtain resistance to progressive collapse. In Ellingwood and Leyendecker (1978), a distinction is made between direct and indirect design, and the following approaches are defined:

Direct Design: Explicit consideration of resistance to progressive collapse during the design process through either

Alternate Path Method: A method that allows local failure to occur but seeks to provide alternate load paths so that the damage is absorbed and major collapse is averted.

Specific Local Resistance Method: A method that seeks to provide sufficient strength to resist failure from accidents or misuse.

Indirect Design: Implicit consideration of resistance to progressive collapse during the design process through the provision of minimum levels of strength, continuity, and ductility.

The general structural integrity of a structure may be tested by analysis to ascertain whether alternate paths around hypothetically collapsed regions exist. Alternatively, alternate-path studies may be used as guides for developing rules for the minimum levels of continuity and ductility needed to apply the indirect design approach to enhance general structural integrity. Specific local resistance may be provided in regions of high risk, because it may be necessary for some element to have sufficient strength to resist abnormal loads for the structure as a whole to develop alternate paths. Ellingwood and Leyendecker (1978) give specific suggestions for the implementation of each of the defined methods.

Guidelines for the Provision of General Structural Integrity. In general, connections between structural components should be ductile and have a capacity for relatively large deformations and energy absorption under the effect of abnormal conditions. This criterion is met in many different ways depending on the structural system used. Details that are appropriate for resistance to moderate wind loads and seismic loads often provide sufficient ductility. In 1999, ASCE issued a state-of-practice report that is a good introduction to the complex field of blast-resistant design (ASCE 1999).

Work with large precast panel structures (Schultz et al. 1977, PCI Committee on Precast Bearing Walls 1976, Fintel and Schultz 1979) provides an example of how to cope with the problem of general structural integrity in a building system that is inherently discontinuous. The provision of ties, combined with careful detailing of connections, can overcome the difficulties associated with such a system. The same kind of methodology and design philosophy can be applied to other systems (Fintel and Annamalai 1979). The ACI *Building Code Requirements for Structural Concrete* (2019a) includes such requirements in Section 4.10.

There are a number of ways of designing for the required integrity to carry loads around severely damaged walls, trusses, beams, columns, and floors. A few examples of design concepts and details are

1. Good plan layout. An important factor in achieving integrity is the proper plan layout of walls and columns. In bearing-wall structures, there should be an arrangement of interior longitudinal walls to support and reduce the span of long sections of crosswall, thus enhancing the stability of individual walls and of the structures

@seismicisolation

as a whole. In the case of local failure, this reduction will also decrease the length of wall likely to be affected.
2. Provide an integrated system of ties among the principal elements of the structural system. These ties may be designed specifically as components of secondary load-carrying systems, which often must sustain very large deformations during catastrophic events.
3. Returns on walls. Returns on interior and exterior walls make them more stable.
4. Changing directions of span of floor slab. Where a one-way floor slab is reinforced to span, with a low safety factor, in its secondary direction if a load-bearing wall is removed, the collapse of the slab will be prevented and the debris loading of other parts of the structure will be minimized. Often, shrinkage and temperature steel will be enough to enable the slab to span in a new direction.
5. Load-bearing interior partitions. The interior walls must be capable of carrying enough load to achieve the change of span direction in the floor slabs.
6. Catenary action of floor slab. Where the slab cannot change span direction, the span will increase if an intermediate supporting wall is removed. In this case, if there is enough reinforcement throughout the slab and enough continuity and restraint, the slab may be capable of carrying the loads by catenary action, though very large deflections will result.
7. Beam action of walls. Walls may be assumed to be capable of spanning an opening if sufficient tying steel at the top and bottom of the walls allows them to act as the web of a beam, with the slabs above and below acting as flanges (Schultz et al. 1977).
8. Redundant structural systems. A secondary load path allows framing to survive removal of key support elements. For example, an upper-level truss or transfer girder system may allow the lower floors of a multistory building to hang from the upper floors in an emergency.
9. Ductile detailing. Avoid low-ductility detailing in elements that might be subject to dynamic loads or very large distortions during localized failures (e.g., consider the implications of shear failures in beams or supported slabs under the influence of building weights falling from above).
10. Provide additional reinforcement to resist blast and load reversal when blast loads are considered in design (ASCE 2010).
11. Consider the use of compartmentalized construction in combination with special moment-resisting frames (as defined in FEMA 1997) in the design of new buildings when considering blast protection.

Although not directly adding structural integrity for the prevention of progressive collapse, the use of special, nonfrangible glass for fenestration can greatly reduce risk to occupants during exterior blasts (ASCE 2010). And to the extent that nonfrangible glass isolates a building's interior from blast shock waves, it can also reduce damage to interior framing elements from exterior blasts (e.g., supported floor slabs could be made to be less likely to fail due to uplift forces).

C1.5 CLASSIFICATION OF BUILDINGS AND OTHER STRUCTURES

C1.5.1 Risk Categorization In the 2010 edition of this standard, a new Table 1.5-2 was added that consolidates the various Importance Factors specified for the several types of loads throughout the standard in one location. This change was made to facilitate the process of finding values for these factors. At the same time, the Importance Factors for wind loads were deleted, because the new wind hazard maps adopted by the standard incorporated consideration of less probable design winds for structures assigned to higher risk categories, negating the need for separate Importance Factors. Similarly, no separate Importance Factors are required for tornado loads, which have been added in the 2022 edition. See Commentary Chapter 26 for further discussion.

The risk categories in Table 1.5-1 are used to relate the criteria for maximum environmental loads or distortions specified in this standard to the consequence of the loads being exceeded for the structure and its occupants. For many years, this standard used the term *occupancy category*, as have the building codes. However, the term *occupancy* as used by the building codes relates primarily to issues associated with fire and life safety protection, as opposed to the risks associated with structural failure. The term *risk category* was adopted in place of the older occupancy category term in the 2010 edition of the standard to distinguish between these two considerations. The risk category numbering is unchanged from that in the previous editions of the standard (ASCE 7-98, -02, and -05), but the criteria for selecting a category have been generalized with regard to structure and occupancy descriptions. The reason for this generalization is that the acceptable risk for a building or structure is an issue of public policy rather than purely a technical one. Model building codes such as the International Building Code (ICC 2021) and NFPA 5000 (2006) contain prescriptive lists of building types by occupancy category. Individual communities can alter these lists when they adopt local codes based on the model code, and individual owners or operators can elect to design individual buildings to higher occupancy categories based on personal risk management decisions. Classification continues to reflect a progression of the anticipated seriousness of the consequence of failure, from the lowest risk to human life (Risk Category I) to the highest (Risk Category IV). Elimination of the specific examples of buildings that fall into each category has the benefit that it eliminates the potential for conflict between the standard and locally adopted codes and also provides individual communities and development teams the flexibility to interpret acceptable risk for individual projects.

Historically, the building codes and the standard have used a variety of factors to determine the occupancy category of a building. These factors include the total number of persons who would be at risk were failure to occur, the total number of persons present in a single room or occupied area, the mobility of the occupants and their ability to cope with dangerous situations, the potential for release of toxic materials, and the loss of services vital to the welfare of the community.

Risk Category I structures generally encompass buildings and structures that normally are unoccupied and that would result in negligible risk to the public should they fail. Structures typically classified in this category have included barns, storage shelters, gatehouses, and similar small structures. Risk Category II includes the vast majority of structures, including most residential, commercial, and industrial buildings, and has historically been considered to contain all those buildings and structures not specifically classified as conforming to another category.

Risk Category III includes buildings and structures that house a large number of persons in one place, such as theaters, lecture halls, and similar assembly uses, and buildings with persons having limited mobility or ability to escape to a safe haven in the event of failure, including elementary schools, prisons, and small health-care facilities. This category has also included structures associated

@seismicisolation

with utilities required to protect the health and safety of a community, including power-generating stations and water-treatment and sewage-treatment plants. It has also included structures housing hazardous substances, such as explosives or toxins, which if released in quantity could endanger the surrounding community, such as structures in petrochemical process facilities containing large quantities of hydrogen sulfide (H_2S) or ammonia.

Failures of power plants that supply electricity on the national grid can cause substantial economic losses and disruption to civilian life when their failures can trigger other plants to go offline in succession. The result can be massive and potentially extended to power outage, shortage, or both, leading to huge economic losses because of idled industries and a serious disruption of civilian life because of inoperable subways, road traffic signals, and so forth. One such event occurred in parts of Canada and the northeastern United States in August 2003.

Failures of water- and sewage-treatment facilities can cause disruption to civilian life because these failures can cause large-scale (but mostly non-life-threatening) public health risks caused by the inability to treat sewage and to provide drinking water.

Failures of major telecommunication centers can cause disruption to civilian life by depriving users of access to important emergency information (using radio, television, and phone communication) and by causing substantial economic losses associated with widespread interruption of business.

Risk Category IV has traditionally included structures the failure of which would inhibit the availability of essential community services necessary to cope with an emergency situation. Buildings and structures typically grouped in Risk Category IV include hospitals, police stations, fire stations, emergency communication centers, and buildings with similar uses.

Ancillary structures required for the operation of Risk Category IV facilities during an emergency also are included in this risk category. When deciding whether an ancillary structure or a structure that supports such functions as fire suppression is in Risk Category IV, the design professional must decide whether failure of the subject structure will adversely affect the essential function of the facility. In addition to Essential Facilities, buildings and other structures containing extremely hazardous materials have been added to Risk Category IV to recognize the potentially devastating effect a release of extremely hazardous materials may have on a population.

The criteria that have historically been used to assign individual buildings and structures to occupancy categories have not been consistent and sometimes have been based on considerations that are more appropriate to fire and life safety than to structural failure. For example, university buildings housing more than a few hundred students have been placed into a higher risk category than office buildings housing the same number of persons.

A rational basis should be used to determine the risk category for structural design, which is primarily based on the number of persons whose lives would be endangered or whose welfare would be affected in the event of failure. Figure C1.5-1 illustrates this concept.

"Lives at risk" pertains to the number of people at serious risk of life loss given a structural failure. The risk category classification is not the same as the building code occupancy capacity, which is mostly based on risk to life from fire. The lives at risk from a structural failure include persons who may be outside the structure in question who are nonetheless put at serious risk by failure of the structure. From this concept, emergency recovery facilities that serve large populations, even though the structure might shelter relatively few people, are moved into the higher risk categories.

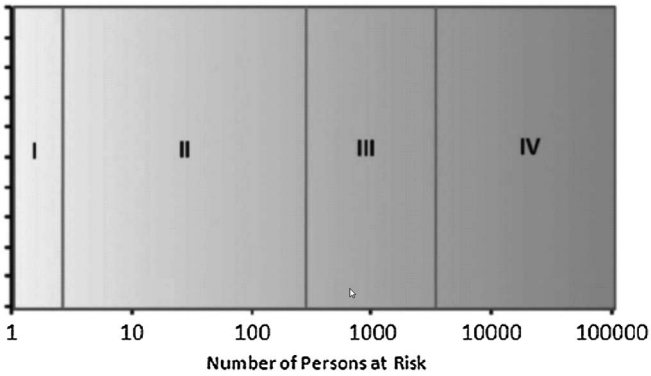

Figure C1.5-1. Approximate relationship between number of lives placed at risk by a failure and risk category.

When determining the population at risk, consideration should also be given to longer-term risks to life than those created during a structural failure. The failure of some buildings and structures, or their inability to function after a severe storm, earthquake, or other disaster, can have far-reaching impact. For example, loss of functionality in one or more fire stations could inhibit the ability of a fire department to extinguish fires, allowing fires to spread and placing many more people at risk. Similarly, the loss of function of a hospital could prevent the treatment of many patients over a period of months.

In Chapters 7, 10, and 11, Importance Factors are presented for the four risk categories identified. The specific Importance Factors differ according to the statistical characteristics of the environmental loads and the manner in which the structure responds to the loads. The principle of requiring more stringent loading criteria for situations in which the consequence of failure may be severe has been recognized in previous versions of this standard by the specification of mean recurrence interval maps for wind speed and ground snow load.

This section now recognizes that there may be situations when it is acceptable to assign multiple risk categories to a building or other structure based on its uses and the types of load conditions being evaluated. For instance, there are circumstances when a building or other structure should appropriately be designed for wind loads associated with risk categories greater than II but would be penalized unnecessarily if designed for seismic loads at that same risk category. An example would be a designated posthurricane recovery shelter in a low seismic area. The building would be classified in Risk Category IV for wind design and in Risk Category II for seismic design.

C1.5.3 Toxic, Highly Toxic, and Explosive Substances A common method of categorizing structures storing toxic, highly toxic, or explosive substances is by the use of a table of exempt amounts of these materials (EPA 1999b, ICC 2000). These references and others are sources of guidance on the identification of materials of these general classifications. A drawback to the use of tables of exempt amounts is that the method cannot handle the interaction of multiple materials. Two materials that are exempt because neither poses a risk to the public by itself may form a deadly combination if combined in a release. Therefore, an alternate and superior method of evaluating the risk to the public of a release of a material is by a hazard assessment as part of an overall risk management plan (RMP).

Buildings and other structures containing toxic, highly toxic, or explosive substances may be classified as Risk Category II

@seismicisolation

structures if it can be demonstrated that the risk to the public from a release of these materials is minimal. Companies that operate industrial facilities typically perform hazard and operability (HAZOP) studies, conduct quantitative risk assessments, and develop risk management and emergency response plans. Federal regulations and local laws mandate many of these studies and plans (EPA 1999a). In addition, many industrial facilities are located in areas remote from the public and have restricted access, which further reduces the risk to the public.

The intent of Section 1.5.2 is for the RMP and the facility's design features that are critical to the effective implementation of the RMP to be maintained for the life of the facility. The RMP and its associated critical design features must be reviewed on a regular basis to ensure that the actual condition of the facility is consistent with the plan. The RMP also should be reviewed whenever consideration is given to the alteration of facility features that are critical to the effective implementation of the RMP.

The RMP generally deals with mitigating the risk to the general public. Risk to individuals outside the facility storing toxic, highly toxic, or explosive substances is emphasized because plant personnel are not placed at as high a risk as the general public because of the plant personnel's training in the handling of toxic, highly toxic, or explosive substances and because of the safety procedures implemented inside the facilities. When these elements (trained personnel and safety procedures) are not present in a facility, then the RMP must mitigate the risk to the plant personnel in the same manner as it mitigates the risk to the general public.

As a result of the prevention program portion of an RMP, buildings and other structures normally falling into Risk Category III may be classified into Risk Category II if means (e.g., secondary containment) are provided to contain the toxic, highly toxic, or explosive substances in the case of a release. To qualify, secondary containment systems must be designed, installed, and operated to prevent migration of harmful quantities of toxic, highly toxic, or explosive substances out of the system to the air, soil, groundwater, or surface water at any time during the use of the structure. This requirement is not to be construed as requiring a secondary containment system to prevent a release of any toxic, highly toxic, or explosive substance into the air. By recognizing that secondary containment shall not allow releases of "harmful" quantities of contaminants, this standard acknowledges that there are substances that might contaminate groundwater but do not produce a sufficient concentration of toxic, highly toxic, or explosive substances during a vapor release to constitute a health or safety risk to the public. Because it represents the "last line of defense," secondary containment does not qualify for the reduced classification.

If the beneficial effect of secondary containment can be negated by external forces, such as the overtopping of dike walls by floodwaters or the loss of liquid containment of an earthen dike because of excessive ground displacement during a seismic event, then the buildings or other structures in question may not be classified into Risk Category II. If the secondary containment is to contain a flammable substance, then implementation of a program of emergency response and preparedness combined with an appropriate fire suppression system would be a prudent action associated with a Risk Category II classification. In many jurisdictions, such actions are required by local fire codes.

Also, as the result of the prevention program portion of an RMP, buildings and other structures containing toxic, highly toxic, or explosive substances also could be classified as Risk Category II for hurricane wind loads when mandatory procedures are used to reduce the risk of release of toxic, highly toxic, or explosive substances during and immediately after these predictable extreme loadings. Examples of such procedures include draining hazardous fluids from a tank when a hurricane is predicted or, conversely, filling a tank with fluid to increase its buckling and overturning resistance. As appropriate to minimize the risk of damage to structures containing toxic, highly toxic, or explosive substances, mandatory procedures necessary for the Risk Category II classification should include preventive measures, such as the removal of objects that might become airborne missiles in the vicinity of the structure.

In previous editions of ASCE 7, definitions of *hazardous* and *extremely hazardous* materials were not provided. Therefore, the determination of the distinction between hazardous and extremely hazardous materials was left to the discretion of the Authority Having Jurisdiction. The change to the use of the terms *toxic* and *highly toxic* based on definitions from federal law (29 CFR 1910.1200 Appendix A with Amendments as of February 1, 2000) has corrected this problem.

Because of the highly quantitative nature of the definitions for toxic and highly toxic in 29 CFR 1910.1200 Appendix A, the General Provisions Task Committee felt that these definitions found in federal law should be directly referenced instead of repeated in the body of ASCE 7. The definitions found in 29 CFR 1910.1200 Appendix A are repeated in the following text for reference.

Highly Toxic. A chemical in any of the following categories:

1. A chemical that has a median lethal dose [LD(50)] of 50 mg or less per kilogram of body weight when administered orally to albino rats weighing between 200 and 300 g each.
2. A chemical that has a median lethal dose [LD(50)] of 200 mg or less per kilogram of body weight when administered by continuous contact for 24 h (or less if death occurs within 24 h) with the bare skin of albino rabbits weighing between 2 and 3 kg each.
3. A chemical that has a median lethal concentration [LC(50)] in air of 200 ppm by volume or less of gas or vapor, or 2 mg per liter or less of mist, fume, or dust, when administered by continuous inhalation for 1 h (or less if death occurs within 1 h) to albino rats weighing between 200 and 300 g each.

Toxic. A chemical in any of the following categories:

1. A chemical that has a median lethal dose [LD(50)] of more than 50 mg per kg, but not more than 500 mg per kg of body weight when administered orally to albino rats weighing between 200 and 300 g each.
2. A chemical that has a median lethal dose [LD(50)] of more than 200 mg per kilogram, but not more than 1,000 mg per kilogram of body weight when administered by continuous contact for 24 h (or less if death occurs within 24 h) with the bare skin of albino rabbits weighing between 2 and 3 kg each.
3. A chemical that has a median lethal concentration [LC(50)] in air of more than 200 parts per million but not more than 2,000 parts per million by volume of gas or vapor, or more than 2 mg per liter but not more than 20 mg per liter of mist, fume, or dust, when administered by continuous inhalation for 1 h (or less if death occurs within 1 h) to albino rats weighing between 200 and 300 g each.

@seismicisolation

C1.6 IN SITU LOAD TESTS

In situ load testing can be used to verify that an existing component or structure has sufficient strength to resist code-required loads with at least the minimum required factor of safety. When there is a question as to the capacity of a component or structure, an in situ load test may be required by the Authority Having Jurisdiction and is subject to review and approval by the Authority Having Jurisdiction.

Load tests involving seismic loads, tsunami loads, and extraordinary loads such as fire, blast, and vehicular impact are beyond the scope of this section.

In situ load tests are typically required to be conducted in accordance with the load test provisions in the approved material design standard (e.g., concrete components and structures should be tested in accordance with Chapter 27 of ACI 318, and steel components and structures should be tested in accordance with Section 5.4 of Appendix 5 of AISC 360). Where the approved material design standard does not provide a load test procedure and acceptance criteria, the registered design professional responsible for the test is tasked with developing and overseeing the load test. At a minimum, the load test should be equal to the factored loads found in Section 2.3.1 and should be adjusted to account for load duration effects where the material being tested is sensitive to such effects. Special care is advisable when developing tests for wood structures, because some wood strength properties are affected by duration of load (e.g., axial compression, flexural, and tensile strength) and some wood strength properties are not (e.g., compression buckling and compression perpendicular to grain). Load testing often involves engineering judgment in terms of developing an appropriate loading mechanism, including both horizontal and vertical loads, as applicable. With respect to load tests for elements that resist dynamic loads, a one-hour test duration may be excessive. For example, in the case of a fall arrest or lifeline anchorage that is used to arrest the movement of a falling person, the maximum load occurs for a fraction of a second; a properly configured load test that sustains the maximum factored design load for a few seconds is more than sufficient to demonstrate that the anchorage has the minimum required strength to serve as a fall arrest anchorage.

There may be some instances where a reduction in design load is appropriate (e.g., an older structure where design live loads are intentionally restricted, like occupancy controls or a posted load restriction on a bridge); if design loads can be reduced in this fashion, in situ tests can incorporate these reduced loads.

CHAPTER C2
COMBINATIONS OF LOADS

C2.1 GENERAL

Loads in this standard are intended for use with design specifications for conventional structural materials, including steel, concrete, masonry, and timber. Some of these specifications are based on allowable stress design, whereas others use strength (or limit states) design. In the case of allowable stress design, design specifications define allowable stresses that may not be exceeded by load effects caused by unfactored loads, that is, allowable stresses contain a factor of safety. In strength design, design specifications provide load factors and, in some instances, resistance factors. Load factors given herein were developed using a first-order probabilistic analysis and a broad survey of the reliabilities inherent in contemporary design practice (Ellingwood et al. 1982, Galambos et al. 1982). It is intended that these load factors be used by all material-based design specifications that adopt a strength design philosophy in conjunction with nominal resistances and resistance factors developed by individual materials-specification-writing groups. Ellingwood et al. (1982) also provide guidelines for materials-specification-writing groups to aid them in developing resistance factors that are compatible, in terms of inherent reliability, with load factors and statistical information specific to each structural material.

The requirement to use either allowable stress design (ASD) or load and resistance factor design (LRFD) dates back to the introduction of load combinations for strength design (LRFD) in the 1982 edition of the standard. An indiscriminate mix of the LRFD and ASD methods may lead to unpredictable structural system performance because the reliability analyses and code calibrations leading to the LRFD load combinations were based on member rather than system limit states. Registered design professionals often design (or specify) cold-formed steel and open web steel joists using ASD and, at the same time, design the structural steel in the rest of the building or other structure using LRFD. Foundations are also commonly designed using ASD, although strength design is used for the remainder of the structure. Using different design standards for these types of elements has not been shown to be a problem. This requirement is intended to permit current industry practice while, at the same time, not permitting LRFD and ASD to be mixed indiscriminately in the design of a structural frame.

C2.2 SYMBOLS

Self-straining forces and effects can be caused by the differential settlement of foundations, creep, shrinkage or expansion in concrete members after placement and similar effects that depend on the material of construction and conditions of constraint, and changes in temperature of members caused by environmental conditions or operational activities during the service life of the structure. See Section C1.3.3 for examples of when self-straining forces and effects may develop.

C2.3 LOAD COMBINATIONS FOR STRENGTH DESIGN

C2.3.1 Basic Combinations Unfactored loads, to be used with these load factors, are the nominal loads of this standard. Load factors are from Ellingwood et al. (1982), with the exception of the load factor of 1.0 for E, based on the more recent NEHRP research on seismic-resistant design (FEMA 2004), the load factor for W, based on the wind speed maps at longer return periods for each risk category, and the load factor for W_T, which was added in ASCE 7-22. The basic idea of the load combination analysis is that in addition to dead load, which is considered to be permanent, one of the principal loads (previously referred to as primary variable loads) takes on its maximum lifetime value while the other loads assume "arbitrary point-in-time" values, the latter being loads that would be measured at any instant of time (Turkstra and Madsen 1980). This is consistent with the manner in which loads actually combine in situations in which strength limit states may be approached. However, nominal loads in this standard are substantially in excess of the arbitrary point-in-time values. To avoid having to specify both a maximum and an arbitrary point-in-time value for each load type, some of the specified load factors are less than unity in combinations 2a through 5a. Load factors in Section 2.3.1, with exceptions described above for E, W, and W_T, are based on a survey of reliabilities inherent in existing design practice (Ellingwood et al. 1982, Galambos et al. 1982).

In design where first-order analysis is permitted, superposition of factored loads can be performed either before or after the analysis. However, when a second-order analysis, which considers the effects of structural deformation on member forces, is used to design members and connections, the load factors must be applied before the analysis; the second-order analysis can be accomplished using a computer program with this capability for frame effects and member effects or by amplifying the results of a first-order analysis through the use of coefficients that amplify the first-order moments for the effects of member deformations or joint displacements. Because second-order effects are nonlinear, the second-order analyses must be conducted under factored load combinations (strength design) or load combinations amplified by the factor of safety (allowable stress design). In this context, second-order effects are the effects of loads acting on the deformed configuration of a structure and include $P-\delta$ effects and $P-\Delta$ effects.

Note that each of the principal loads, including the dead load, is a random variable. The degree of variability in each load is reflected in the associated load factor for the principal load; the other load factors provide the companion values.

@seismicisolation

Table C2.3-1. Principal Loads for Strength Design Load Combinations.

	Load Combination	Principal Load
1a	$1.4D$	D
2a	$1.2D + 1.6L + (0.5L_r \text{ or } 0.3S \text{ or } 0.5R)$	L
3a	$1.2D + (1.6L_r \text{ or } 1.0S \text{ or } 1.6R) + (L \text{ or } 0.5W)$	L_r or S or R
4a	$1.2D + 1.0(W \text{ or } W_T) + L + (0.5L_r \text{ or } 0.3S \text{ or } 0.5R)$	W or W_T
5a	$0.9D + 1.0(W \text{ or } W_T)$	W or W_T
6	$1.2D + E_v + E_h + L + 0.15S$	E
7	$0.9D - E_v + E_h$	E

The principal loads in the load combinations are identified in Table C2.3-1. The load factor on wind loads, in combinations 4a and 5a of Section 2.3.1 and on earthquake loads in combinations 6 and 7 of Section 2.3.6, were changed to 1.0 in previous editions of ASCE 7 when the maps for design wind speed and design seismic acceleration were modified to support a risk-consistent design methodology, as described in Chapters 21 and 26. The tornado load, W_T, was newly added in ASCE 7-22, as described in Chapter 32.

Exception 2 permits the companion load, S, that appears in combinations 2a and 4a to be the balanced snow load defined in Sections 7.3 for flat roofs and 7.4 for sloped roofs. Drifting and unbalanced snow loads, as principal loads, are covered by combination 3a.

Exception 3 permits the removal of the companion load, S, from combination 4a where using W_T, since tornadoes are overwhelmingly a warm-weather phenomenon.

Load combinations 5a and 7 apply specifically to the case in which the structural actions, due to lateral forces and gravity loads, counteract one another.

Load combination requirements in Section 2.3 only apply to strength limit states. Serviceability limit states and associated load factors are covered in Appendix C of this standard.

Historically, this standard has provided specific procedures for determining magnitudes of dead, occupancy live, wind, snow, and earthquake loads. Other loads, not traditionally considered by this standard, may also require consideration in design. Some of these loads may be important in certain material specifications and are included in the load criteria to enable uniformity to be achieved in the load criteria for different materials. However, statistical data on these loads are limited or nonexistent, and the same procedures used to obtain load factors and load combinations in Section 2.3.1 cannot be applied at the present time. Accordingly, load factors for fluid load (F) and lateral pressure caused by soil and water in soil (H) have been chosen to yield designs that would be similar to those obtained with existing specifications, if appropriate adjustments consistent with the load combinations in Section 2.3.1 were made to the resistance factors. Further research is needed to develop more accurate load factors.

Fluid load, F, defines structural actions in structural supports, framework, or foundations of a storage tank, vessel, or similar container caused by stored liquid products. The product in a storage tank shares characteristics of both dead and live loads. It is similar to a dead load in that its weight has a maximum calculated value, and the magnitude of the actual load may have a relatively small dispersion. However, it is not permanent; emptying and filling cause fluctuating forces in the structure, the maximum load may be exceeded by overfilling, and densities of stored products in a specific tank may vary.

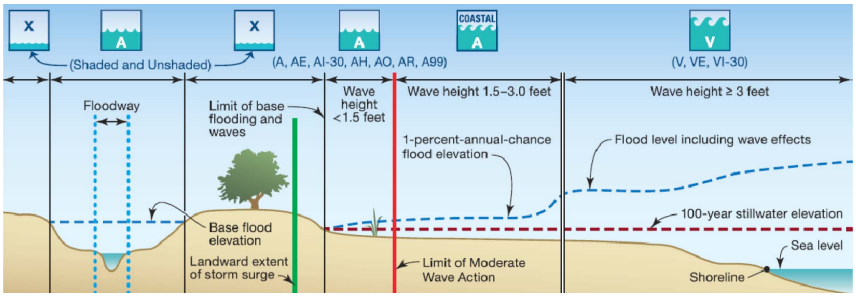
Uncertainties in lateral forces from bulk materials, included in H, are higher than those in fluids, particularly when dynamic effects are introduced as the bulk material is set in motion by filling or emptying operations. Accordingly, the load factor for such loads is set equal to 1.6.

Where H acts as a resistance, a factor of 0.9 is suggested if the passive resistance is computed with a conservative bias. The intent is that soil resistance be computed for a deformation limit appropriate for the structure being designed, not at the ultimate passive resistance. Thus, an at-rest lateral pressure, as defined in the technical literature, would be conservative enough. Higher resistances than at-rest lateral pressure are possible, given appropriate soil conditions. Fully passive resistance would likely never be appropriate because the deformations necessary in the soil would likely be so large that the structure would be compromised. Furthermore, there is a great uncertainty in the nominal value of passive resistance, which would also argue for a lower factor on H, should a conservative bias not be included.

When H is due to lateral earth pressure, the additional lateral earth pressure from fixed or moving surcharge loads is added to H, as required by Section 3.2.1. Uncertainties in lateral forces from earth pressure are fairly high, such that the load factor for these lateral loads is set equal to 1.6. Therefore, the load factor used for the additional lateral load from fixed or moving surcharge loads is also set equal to 1.6, even if the gravity weight of the surcharge loads is well defined.

C2.3.2 Load Combinations Including Flood Load The nominal flood load, F_a, is based on the 100-year flood (Section 5.1). The recommended flood load factor of 2.0 in V-Zones and Coastal A-Zones is based on a statistical analysis of flood loads associated with hydrostatic pressures, pressures caused by steady overland flow, and hydrodynamic pressures caused by waves, as specified in Section 5.4.

The flood load criteria were derived from an analysis of hurricane-generated storm tides produced along the United States East and Gulf coasts (Kriebel et al. 1998), where storm tide is defined as the water level above mean sea level resulting from wind-generated storm surge added to randomly phased astronomical tides. Hurricane wind speeds and storm tides were simulated at 11 coastal sites based on historical storm climatology and on accepted wind speed and storm surge models. The resulting wind speed and storm tide data were then used to define probability distributions of wind loads and flood loads using wind and flood load equations specified in Sections 5.3 and 5.4. Load factors for these loads were then obtained using established reliability methods (Ellingwood et al. 1982, Galambos et al. 1982) and achieve approximately the same level of reliability as do combinations involving wind loads acting without floods. The relatively high flood load factor stems from the high variability in floods relative to other environmental loads. The presence of $2.0F_a$ in both combinations 4b and 5b in V-Zones and Coastal A-Zones is the result of high stochastic dependence between extreme wind and flood in hurricane-prone coastal zones. The $2.0F_a$ also applies in coastal areas subject to northeasters, extratropical storms, or coastal storms other than hurricanes, where a high correlation exists between extreme wind and flood.



While flooding can occur in storms that produce tornadoes, the spatiotemporal correlation between tornadoes and flooding is much less than that between hurricane winds and flooding. Therefore, the load combinations from Section 2.3.2 maximizing flood loads do not include arbitrary point-in-time tornado loads.

@seismicisolation

Flood loads are unique in that they are initiated only after the water level exceeds the local ground elevation. As a result, the statistical characteristics of flood loads vary with ground elevation. The load factor 2.0 is based on calculations (including hydrostatic, steady flow, and wave forces) with stillwater flood depths ranging from approximately 4 to 9 ft (1.2 to 2.7 m) [average stillwater flood depth of approximately 6 ft (1.8 m)] and applies to a wide variety of flood conditions. For lesser flood depths, load factors exceed 2.0 because of the wide dispersion in flood loads relative to the nominal flood load. As an example, load factors appropriate to water depths slightly less than 4 ft (1.2 m) equal 2.8 (Mehta et al. 1998). However, in such circumstances, the flood load is generally small. Thus, the load factor 2.0 is based on the recognition that flood loads of most importance to structural design occur in situations where the depth of flooding is greatest.

The 1.6 load factor, specified for H loads in Section 2.3.1, can be applied for groundwater induced uplift pressures. Figure C2.3-1 illustrates the flood zones and load factors for F_a and H.

C2.3.3 Load Combinations Including Atmospheric Ice and Wind-on-Ice Loads Load combinations 2b and 4c in Section 2.3.3 and load combination 3b in Section 2.4.3 include the simultaneous effects of snow loads, as defined in Chapter 7 and atmospheric ice loads, as defined in Chapter 10. Load combinations 4c and 5c in Sections 2.3.3 and load combinations 3b and 7c in

	Flood Zone			
	X Zone	A Zone	Coastal A Zone	V Zone
Strength Design Load Factor on F_a for Structural Elements	N/A	1.0	2.0	2.0
	X Zone	A Zone	Coastal A Zone	V Zone
Strength Design Load Factor on H for Structural Elements (hydrostatic uplift and lateral pressure due to groundwater)	1.6	1.6	1.6	1.6
	X Zone	A Zone	Coastal A Zone	V Zone
Allowable Stress Design Load Factor on F_a for Structural Elements	N/A	0.75	1.5	1.5
	X Zone	A Zone	Coastal A Zone	V Zone
Allowable Stress Design Load Factor on H for Structural Elements (hydrostatic uplift and lateral pressure due to groundwater)	1.0	1.0	1.0	1.0

Figure C2.3-1. Flood zones and ASCE 7 load factors for F_a and H for (from right to left in figure): coastal flood zones (V Zone, Coastal A Zone, and A Zone), areas outside the 100-year floodplain (X Zone shaded are areas inside the 500-year flood plain and X Zone unshaded are areas outside the 500-year flood plain), and riverine flood zone (A Zone). See FEMA (2005, 2011) for definitions of flood zones.

@seismicisolation

Section 2.4.3 introduce the simultaneous effect of wind on the atmospheric ice. The ice load, D_i, and the wind load on the atmospheric ice, W_i, in combination, correspond to an event with approximately a 500-year mean recurrence interval (MRI). Accordingly, the load factors on W_i and D_i are set equal to 1.0 and 0.7 in Sections 2.3.3 and 2.4.3, respectively. The 0.7 load factor on W_i and D_i in Section 2.4.3 aligns allowable stress design to have reliabilities for atmospheric ice loads consistent with the definition of wind and ice loads in Chapter 10 of this standard, which is based on strength principles. The snow loads defined in Chapter 7 are based on measurements of frozen precipitation accumulated on the ground, which includes snow, ice caused by freezing rain, and rain that falls onto snow and later freezes. Thus, the effects of freezing rain are included in the snow loads for roofs, catwalks, and other surfaces to which snow loads are normally applied. The atmospheric ice loads defined in Chapter 10 are applied simultaneously to those portions of the structure on which ice caused by freezing rain, in-cloud icing, or snow accretion that are not subject to the snow loads in Chapter 7. A trussed tower installed on the roof of a building is one example. The snow loads from Chapter 7 would be applied to the roof with the atmospheric ice loads from Chapter 10 applied to the trussed tower. Section 2.3.3 load combination 4c ($1.2D + L + D_i + W_i + 0.3S$) or Section 2.4.3 load combination 3b ($D + 0.7D_i + 0.7W_i + 0.7S$) are applicable. If a trussed tower has working platforms, the snow loads would be applied to the surface of the platforms, similar to a roof, with the atmospheric ice loads applied to the tower. Section 2.3.3 load combination 4c would reduce to $1.2D + D_i$ for cases for which the live load, wind on ice load, and snow load are zero. Section 2.4.3 load combination 3b would similarly reduce to $D + 0.7D_i$. If a sign is mounted on a roof, the snow loads would be applied to the roof and the atmospheric ice loads to the sign.

C2.3.4 Load Combinations Including Self-Straining Forces and Effects Self-straining forces and effects should be calculated based on a realistic assessment of the most probable values rather than the upper bound values of the variables. The most probable value is the value that can be expected at any arbitrary point in time.

When self-straining forces and effects are combined with dead loads as the principal action, a load factor of 1.2 may be used. However, when more than one variable load is considered and self-straining forces and effects are considered as a companion load, the load factor may be reduced if it is unlikely that the principal and companion loads will attain their maximum values at the same time. The load factor applied to T should not be taken as less than a value of 1.0.

If only limited data are available to define the magnitude and frequency distribution of the self-straining forces and effects, then its value must be estimated conservatively. Estimating the uncertainty in the self-straining forces and effects may be complicated by variation of the material stiffness of the member or structure under consideration.

When checking the capacity of a structure or structural element to withstand the effects of self-straining forces and effects, the following load combinations should be considered.

When using strength design:

$$1.2D + 1.2T + 0.5L$$

$$1.2D + 1.6L + 1.0T$$

These combinations are not all-inclusive, and judgment is necessary in some situations. For example, where roof live loads or snow loads are significant and could conceivably occur simultaneously with self-straining forces and effects, their effect should be included. The design should be based on the load combination causing the most unfavorable effect.

C2.3.5 Load Combinations for Nonspecified Loads Engineers may wish to develop load criteria for strength design that are consistent with the requirements of this standard in some situations for which the standard provides no information on loads or load combinations. They also may wish to consider loading criteria for special situations, as required by the client in performance-based engineering (PBE) applications, in accordance with Section 1.3.1.3. Groups responsible for strength design criteria for design of structural systems and elements may wish to develop resistance factors that are consistent with the standard. Such load criteria should be developed using a standardized procedure to ensure that the resulting factored design loads and load combinations will lead to target reliabilities (or levels of performance) that can be benchmarked against the common load criteria in Section 2.3.1. Section 2.3.5 permits load combinations for strength design to be developed through a standardized method that is consistent with the methodology used to develop the basic combinations that appear in Section 2.3.1.

The load combination requirements in Section 2.3.1 and the resistance criteria for structural steel in AISC 360 (2022), for structural stainless steel in AISC 370 (2021), for cold-formed steel in AISI S100 (2020), for structural concrete in ACI 318 (2019), for structural aluminum in the *Specification for Aluminum Structures* (Aluminum Association 2020), for engineered wood construction in *AWC NDS-2018 National Design Specification for Wood Construction* (2017), and for masonry in TMS 402-16, *Building Code Requirements and Specifications for Masonry Structures and Companion Commentaries* (2016), are based on modern concepts of structural reliability theory. In probability-based limit states design (PBLSD), the reliability is measured by a reliability index, β, which is related (approximately) to the limit state probability by $P_f = \varphi(-\beta)$. The approach taken in PBLSD was to

1. Determine a set of reliability objectives or benchmarks, expressed in terms of β, for a spectrum of traditional structural member designs involving steel, reinforced concrete, engineered wood, and masonry. Gravity load situations were emphasized in this calibration exercise, but wind and earthquake loads were considered as well. A group of experts from material specifications participated in assessing the results of this calibration and selecting target reliabilities. Thus, the reliability benchmarks identified are *not* the same for all limit states; if the failure mode is relatively ductile and consequences are not serious, β tends to be in the range 2.5 to 3.0, whereas if the failure mode is brittle and consequences are severe, β is 4.0 or more.
2. Determine a set of load and resistance factors that best meet the reliability objectives identified in Item 1 in an overall sense, considering the scope of structures that might be designed by this standard and the material specifications and codes that reference it.

The load combination requirements appearing in Section 2.3.1 used this approach. They are based on a "principal action–companion action" format, in which one load is taken at its maximum value while other loads are taken at their point-in-time values. Based on the comprehensive reliability analysis performed to support their development, it was found that these load factors are well approximated by

$$\gamma_Q = (\mu_Q / Q_n)(1 + \alpha_Q \beta V_Q) \qquad \text{(C2.3-1)}$$

@seismicisolation
@seismicisolation

where

μ_Q = Mean load,
Q_n = Nominal load from other chapters in this standard,
V_Q = Coefficient of variation in the load,
β = Reliability index, and
α_Q = Sensitivity coefficient that is approximately equal to 0.8 when Q is a principal action and 0.4 when Q is a companion action.

This approximation is valid for a broad range of common probability distributions used to model structural loads. The load factor is an increasing function of the bias in the estimation of the nominal load, the variability in the load, and the target reliability index, as common sense would dictate.

As an example, the load factors in combination 2a of Section 2.3.1 are based on achieving a β of approximately 3.0 for a ductile limit state with moderate consequences (e.g., formation of first plastic hinge in a steel beam). For live load acting as a principal action, $\mu_Q/Q_n = 1.0$ and $V_Q = 0.25$; for live load acting as a companion action, $\mu_Q/Q_n \approx 0.3$ and $V_Q \approx 0.6$. Substituting these statistics into Equation (C2.3-1), $\gamma_Q = 1.0[1 + 0.8(3)(0.25)] = 1.6$ (principal action) and $\gamma_Q = 0.3[1 + 0.4(3)(0.60)] = 0.52$ (companion action). ASCE Standard 7-05 (2005) stipulates 1.60 and 0.50 for these live load factors in combinations 2a and 3a. If an engineer wished to design for a limit state probability that is less than the standard case by a factor of approximately 10, β would increase to approximately 3.7, and the principal live load factor would increase to approximately 1.74.

Similarly, resistance factors that are consistent with the aforementioned load factors are well approximated for most materials by

$$\varphi = (\mu_R/R_n)\exp[-\alpha_R\beta V_R] \qquad \text{(C2.3-2)}$$

where

μ_R = Mean strength,
R_n = Code-specified strength,
V_R = Coefficient of variation in strength, and
α_R = Sensitivity coefficient equal to approximately 0.7.

For the limit state of yielding in an ASTM A992 (2011) steel tension member with specified yield strength of 50 ksi (345 MPa), $\mu_R/R_n = 1.06$ (under a static rate of load) and $V_R = 0.09$. Equation (C2.3-2) then yields $\varphi = 1.06\exp[-(0.7)(3.0)(0.09)] = 0.88$. The resistance factor for yielding in tension in Section D of the AISC Specification (2022) is 0.9. If a different performance objective were to require that the target limit state probability be decreased by a factor of 10, then φ would decrease to 0.84, a reduction of about 7%. Engineers wishing to compute alternative resistance factors for engineered wood products, and other structural components where duration-of-load effects might be significant, are advised to review the reference materials provided by their professional associations before using Equation (C2.3-2).

There are two key issues that must be addressed to use Equations (C2.3-1) and (C2.3-2): selection of reliability index, β, and determination of the load and resistance statistics.

The reliability index controls the safety level, and its selection should depend on the mode and consequences of failure. The loads and load factors in this standard do not explicitly account for higher reliability indexes normally desired for brittle failure mechanisms or more serious consequences of failure. Common standards for design of structural materials often do account for such differences in their resistance factors (for example, the design of connections under AISC or the design of columns under ACI). Tables 1.3-1 and 1.3-2 provide general guidelines for selecting target reliabilities consistent with the extensive calibration studies performed earlier to develop the load requirements in Section 2.3.1 and the resistance factors in the design standards for structural materials. The reliability indexes in those earlier studies were determined for structural members based on a service period of 50 years. System reliabilities are higher to a degree that depends on structural redundancy and ductility. The probabilities represent, *in order of magnitude*, the associated annual member failure rates for those who would find this information useful in selecting a reliability target.

The load requirements in Sections 2.3.1 through 2.3.3 are supported by extensive peer-reviewed statistical databases, and the values of mean and coefficient of variation, μ_Q/Q_n and V_Q, are well established. This support may not exist for other loads that have traditionally not been covered by this standard. Similarly, the statistics used to determine μ_R/R_n and V_R should be consistent with the underlying material specification. When statistics are based on small-batch test programs, all reasonable sources of end-use variability should be incorporated in the sampling plan. The engineer should document the basis for all statistics selected in the analysis and submit the documentation for review by the Authority Having Jurisdiction. Such documents should be made part of the permanent design record.

The engineer is cautioned that load and resistance criteria necessary to achieve a reliability-based performance objective are coupled through the common term β in Equations (C2.3-1) and (C2.3-2). Adjustments to the load factors without corresponding adjustments to the resistance factors will lead to an unpredictable change in structural performance and reliability.

C2.3.6 Basic Combinations with Seismic Load Effects The seismic load effect, E, is combined with the effects of other loads. For strength design, the load combinations with E in Section 2.3.6 include the horizontal and vertical seismic load effects of Sections 12.4.2.1 and 12.4.2.2, respectively. Similarly, the basic load combinations for allowable stress design with E in Section 2.4.5 include the same seismic load effects.

The seismic load effect including overstrength factor, E_m, is combined with other loads. The purpose for load combinations with overstrength factor is to approximate the maximum seismic load combination for the design of critical elements, including discontinuous systems, transfer beams and columns supporting discontinuous systems, and collectors. The allowable stress increase for load combinations with overstrength is to provide compatibility with past practice.

Load combination 6 addresses the combined structural actions (member forces) arising from snow and earthquake effects. The contribution of snow to effective seismic weight is defined in Section 12.7.2. The full snow load need not be considered in the effective seismic weight, as discussed in Section C12.7.2.

C2.3.7 Alternative Method for Loads from Water in Soil The effect of ground water pressure in soil, H_w, is decoupled from soil pressure and computed per Section 3.3; however, the effect of buoyancy is still included in the computation of lateral soil pressure, H_{eb}. The basic method includes H_w as part of H, which does not account for the uncertainty in the elevation of the groundwater. The 1.6 load factor in the basic method effectively adjusts the density of water.

C2.4 LOAD COMBINATIONS FOR ALLOWABLE STRESS DESIGN

C2.4.1 Basic Combinations The load combinations listed cover those loads for which specific values are given in other parts of this standard. Design should be based on the load combination causing the most unfavorable effect. In some cases, this may occur when one or more loads are not acting. No safety factors have been applied to these loads because such

@seismicisolation
@seismicisolation

Table C2.4-1. Principal Loads for Allowable Stress Design Load Combinations.

	Load Combination	Principal Load
1a	D	D
2a	$D + L$	L
3a	$D + (L_r \text{ or } 0.7S \text{ or } R)$	L_r or S or R
4a	$D + 0.75L + 0.75(L_r \text{ or } 0.7S \text{ or } R)$	L
5a	$D + 0.6(W \text{ or } W_T)$	W or W_T
6a	$D + 0.75L + 0.75(0.6(W \text{ or } W_T)) + 0.75(L_r \text{ or } 0.7S \text{ or } R)$	W or W_T
7a	$0.6D + 0.6(W \text{ or } W_T)$	W or W_T
8	$D + 0.7E_v + 0.7E_{mh}$	E
9	$D + 0.525E_v + 0.525E_{mh} + 0.75L + 0.1S$	E
10	$0.6D - 0.7E_v + 0.7E_{mh}$	E

factors depend on the design philosophy adopted by the particular material specification. The principal load, or maximum variable load, in the load combinations is identified in Table C2.4-1.

Wind, tornado, and earthquake loads need not be assumed to act simultaneously. However, the most unfavorable effects of each should be considered separately in design, where appropriate. In some instances, forces caused by wind or tornado might exceed those caused by earthquake, and ductility requirements might be determined by earthquake loads.

Load combinations 7a in Section 2.4.1 and 10 in Section 2.4.5 address the situation in which the effects of lateral or uplift forces counteract the effect of gravity loads. This action eliminates an inconsistency in the treatment of counteracting loads in allowable stress design and strength design and emphasizes the importance of checking stability. In such a situation, the reliability of structural components and systems is determined mainly by the large variability in the destabilizing load (Ellingwood and Li 2009), and the factor 0.6 on dead load is necessary for maintaining comparable reliability between strength design and allowable stress design. The earthquake load effect is multiplied by 0.7 to align allowable stress design for earthquake effects with the definition of E in Section 11.3 of this standard, which is based on strength principles.

Most loads, other than dead loads, vary significantly with time. When these variable loads are combined with dead loads, their combined effect should be sufficient to reduce the risk of unsatisfactory performance to an acceptably low level. However, when more than one variable load is considered, it is extremely unlikely that they will all attain their maximum value at the same time (Turkstra and Madsen 1980). Accordingly, some reduction in the total of the combined load effects is appropriate. This reduction is accomplished through the 0.75 load combination factor. The 0.75 factor applies only to the variable loads because the dead loads (or stresses caused by dead loads) do not vary in time.

Historically, many materials standards and building codes permitted a 1/3 increase in allowable stresses for load combinations that included either wind or seismic. Justifications for the 1/3 increase included the combined load effect as discussed, the ability of some materials to exhibit higher strength under short-term loading, and the apparent acceptability of a reduced factor of safety for these loadings. This standard addresses the low likelihood of simultaneous maximum load effect as discussed in the preceding paragraph. The acceptable probability of failure is explicitly addressed in the load factors applied in the strength design load combinations; the factors in the allowable stress design combinations are intended to provide a rough equivalence to the strength combinations. Where the strength of the material depends on rate or duration of loading, such as is the case with some soils and wood, it is permitted to adjust the allowable stresses to account for the increased strength under short-term loading, for example, the load duration factor (C_d) in AWC (2017). However, the simple 1/3 increase for all load combinations that involve wind or seismic is no longer permitted.

Exception 1 permits the companion load, S, appearing in combinations 4a and 6a to be the balanced snow load defined in Sections 7.3 for flat roofs and 7.4 for sloped roofs. Drifting and unbalanced snow loads, as principal loads, are covered by combination 3a.

When wind or tornado forces act on a structure, the structural action causing uplift at the structure–foundation interface is less than would be computed from the peak lateral force because of area averaging. Area averaging of wind forces occurs for all structures. In the method used to determine the wind forces for enclosed structures, the area-averaging effect is already taken into account in the data analysis leading to the pressure coefficients, C_p [or (GC_p)]. However, in the design of tanks and other industrial structures, the wind force coefficients, C_f, provided in the standard do not account for area averaging. For this reason, Exception 2 permits the wind or tornado loads to be reduced by 10% in the design of nonbuilding structure foundations and self-anchored ground-supported tanks. For different reasons, a similar approach is already provided for seismic actions in Section 2.4.1, Exception 2.

Exception 3 permits removal of the companion load, S, from combination 6a, where using W_T, since tornadoes are overwhelmingly a warm-weather phenomenon.

C2.4.2 Load Combinations Including Flood Load See Section C2.3.2. The multiplier on F_a aligns allowable stress design for flood load with strength design.

C2.4.3 Load Combinations Including Atmospheric Ice and Wind-on-Ice Loads See Section C2.3.3.

C2.4.4 Load Combinations Including Self-Straining Forces and Effects When using allowable stress design, determination of how self-straining forces and effects should be considered together with other loads should be based on the considerations discussed in Section C2.3.4. For typical situations, the following load combinations should be considered for evaluating the effects of self-straining forces and effects together with dead and live loads:

$$1.0D + 1.0T$$

$$1.0D + 0.75(L + T)$$

These combinations are not all-inclusive, and in some situations, judgment is necessary. For example, where roof live loads or snow loads are significant and could conceivably occur simultaneously with self-straining forces, their effect should be included.

@seismicisolation
@seismicisolation

The design should be based on the load combination causing the most unfavorable effect.

C2.4.5 Basic Combinations with Seismic Load Effects Load combination 9 addresses the combined structural actions (member forces) arising from snow and earthquake effects. The contribution of snow to effective seismic weight is defined in Section 12.7.2. The full snow load need not be considered in the effective seismic weight, as discussed in Section C12.7.2.

Exception 2 in Section 2.4.5, for special reinforced masonry walls, is based on the combination of three factors that yield a conservative design for overturning resistance under the seismic load combination:

1. The basic allowable stress for reinforcing steel is 40% of the specified yield.
2. The minimum reinforcement required in the vertical direction provides a protection against the circumstance where the dead and seismic loads result in a very small demand for tension reinforcement.
3. The maximum reinforcement limit prevents compression failure under overturning.

Of these, the low allowable stress in the reinforcing steel is the most significant. This exception should be deleted when and if the standard for design of masonry structures substantially increases the allowable stress in tension reinforcement.

C2.5 LOAD COMBINATIONS FOR EXTRAORDINARY EVENTS

Section 2.5 advises the structural engineer that certain circumstances might require structures to be checked for low-probability events such as fire, explosions, and vehicular impact. Since the 1995 edition of ASCE Standard 7, Commentary C2.5 has provided a set of load combinations that were derived using a probabilistic basis similar to that used to develop the load combination requirements for ordinary loads in Section 2.3. In recent years, social and political events have led to an increasing desire on the part of architects, structural engineers, project developers, and regulatory authorities to enhance design and construction practices for certain buildings to provide additional structural robustness and to lessen the likelihood of disproportionate collapse if an abnormal event were to occur. Several federal, state, and local agencies have adopted policies that require new buildings and structures to be constructed with such enhancements of structural robustness (GSA 2003, DOD 2009). Typically, robustness is assessed by notional removal of key load-bearing structural elements, followed by a structural analysis to assess the ability of the structure to bridge over the damage (often denoted alternative path analysis). Concurrently, advances in structural engineering for fire conditions (e.g., AISC 2022, Appendix 4; AISC 2021, Appendix 4 and Appendix 7) raise the prospect that new structural design requirements for fire safety will supplement the existing deemed-to-satisfy provisions in the next several years. To meet these needs, the load combinations for extraordinary events in ASCE 7-10 (ASCE 2010) were moved to Section 2.5 of this standard from Section C2.5, where they appeared in previous editions.

These provisions are not intended to supplant traditional approaches to ensure fire endurance based on standardized time–temperature curves and code-specified endurance times. Current code-specified endurance times are based on the ASTM E119 (2014) time–temperature curve under full allowable design load.

Extraordinary events arise from service or environmental conditions that are traditionally not considered explicitly in design of ordinary buildings and other structures. Such events are characterized by a low probability of occurrence and usually a short duration. Few buildings are ever exposed to such events, and statistical data to describe their magnitude and structural effects are rarely available. Included in the category of extraordinary events would be fire, explosions of volatile liquids or natural gas in building service systems, sabotage, vehicular impact, misuse by building occupants, and subsidence (not settlement) of subsoil. The occurrence of any of these events is likely to lead to structural damage or failure. If the structure is not properly designed and detailed, this local failure may initiate a chain reaction of failures that propagates throughout a major portion of the structure and leads to a potentially catastrophic partial, or total, collapse. Although all buildings are susceptible to such collapses in varying degrees, construction that lacks inherent continuity and ductility is particularly vulnerable (Taylor 1975, Breen and Siess 1979, Carper and Smilowitz 2006, Nair 2006, NIST 2007).

Good design practice requires that structures be robust and that their safety and performance not be sensitive to uncertainties in loads, environmental influences, and other situations not explicitly considered in design. The structural system should be designed in such a way that if an extraordinary event occurs, the probability of damage disproportionate to the original event is sufficiently small (Carper and Smilowitz 2006, NIST 2007). The philosophy of designing to limit the spread of damage, rather than to prevent damage entirely, is different from the traditional approach to designing to withstand dead, live, snow, and wind loads but is similar to the philosophy adopted in modern earthquake-resistant design.

In general, structural systems should be designed with sufficient continuity and ductility that alternate load paths can develop after individual member failure so that failure of the structure as a whole does not ensue. At a simple level, continuity can be achieved by requiring development of a minimum tie force, say 20 kN/m (1.37 kip/ft) between structural elements (NIST 2007). Member failures may be controlled by protective measures that ensure that no essential load-bearing member is made ineffective as a result of an accident, although this approach may be more difficult to implement. Where member failure would inevitably result in a disproportionate collapse, the member should be designed for a higher degree of reliability (NIST 2007).

Design limit states include loss of equilibrium as a rigid body, large deformations leading to significant second-order effects, yielding or rupture of members or connections, formation of a mechanism, and instability of members or the structure as a whole. These limit states are the same as those considered for other load events, but the load-resisting mechanisms in a damaged structure may be different, and sources of load-carrying capacity that normally would not be considered in ordinary ultimate limit states design, such as arch, membrane, or catenary action, may be included. The use of elastic analysis underestimates the load-carrying capacity of the structure (Marjanishvili and Agnew 2006). Materially or geometrically nonlinear or plastic analyses may be used, depending on the response of the structure to the actions.

Specific design provisions to control the effect of extraordinary loads and risk of progressive failure are developed with a probabilistic basis (Ellingwood and Leyendecker 1978, Ellingwood and Corotis 1991, Ellingwood and Dusenberry 2005). One can either reduce the likelihood of the extraordinary event or design the structure to withstand or absorb damage from the event if it occurs. Let F be the event of failure (damage or collapse) and A be the event that a structurally damaging event occurs. The probability of failure due to event A is

@seismicisolation
@seismicisolation

$$P_f = P(F|A)P(A) \quad \text{(C2.5-1)}$$

in which $P(F|A)$ is the conditional probability of failure of a damaged structure and $P(A)$ is the probability of occurrence of event A. The separation of $P(F|A)$ and $P(A)$ allows one to focus on strategies for reducing risk. $P(A)$ depends on siting, controlling the use of hazardous substances, limiting access, and other actions that are essentially independent of structural design. In contrast, $P(F|A)$ depends on structural design measures, ranging from minimum provisions for continuity to a complete post-damage structural evaluation.

The probability, $P(A)$, depends on the specific hazard. Limited data for severe fires, gas explosions, bomb explosions, and vehicular collisions indicate that the event probability depends on building size, measured in dwelling units or square footage, and ranges from about 0.2×10^{-6}/dwelling unit/year to about 8.0×10^{-6}/dwelling unit/year (NIST 2007). Thus, the probability that a building structure is affected may depend on the number of dwelling units (or square footage) in the building. If one were to set the conditional limit state probability, $P(F|A) = 0.05 - 0.10$, however, the annual probability of structural failure from Equation (C2.5-1) would be less than 10^{-6}, placing the risk in the low-magnitude background along with risks from rare accidents (Pate-Cornell 1994).

Design requirements corresponding to this desired $P(F|A)$ can be developed using first-order reliability analysis if the limit state function describing structural behavior is available (Ellingwood and Dusenberry 2005). The structural action (force or constrained deformation) resulting from extraordinary event A used in design is denoted A_k. Only limited data are available to define the frequency distribution of the load (NIST 2007; Ellingwood and Dusenberry 2005). The uncertainty in the load caused by the extraordinary event is encompassed in the selection of a conservative A_k, and thus the load factor on A_k is set equal to 1.0, as is done in the earthquake load combinations in Section 2.3. The dead load is multiplied by the factor 0.9 if it has a stabilizing effect; otherwise, the load factor is 1.2, as it is with the ordinary combinations in Sections 2.3.1 and 2.3.6. Load factors less than 1.0 on the companion actions reflect the small probability of a simultaneous occurrence of the extraordinary load and the design live, snow, or wind load. The companion actions $0.5L$ and $0.2S$ correspond, approximately, to the mean of the yearly maximum live and snow loads (Chalk and Corotis 1980, Ellingwood 1981). The companion action in Equation (2.5-1) includes only snow load because the probability of a coincidence of A_k with L_r or R, which have short durations in comparison with S, is negligible. A similar set of load combinations for extraordinary events appears in *Eurocode 1* (2006).

The term $0.2W$ that previously appeared in these combinations has been removed and has been replaced by a requirement to check lateral stability. One approach for meeting this requirement, which is based on recommendations of the Structural Stability Research Council (Galambos 1998), is to apply lateral notional forces, $N_i = 0.002\Sigma P_i$, at level i, in which ΣP_i = gravity force from Equations (2.5-1) or (2.5-2) act at level i, in combination with the loads stipulated in Equations (2.5-1) or (2.5-2). Note that Equation (1.4-1) stipulates that when checking general structural integrity, the lateral forces acting on an intact structure shall equal $0.01W_x$, where W_x is the dead load at level x.

CHAPTER C3
DEAD LOADS, SOIL LOADS, AND HYDROSTATIC PRESSURE

C3.1 DEAD LOADS

C3.1.2 Weights of Materials of Construction To establish uniform practice among designers, it is desirable to present a list of materials generally used in building construction, together with their proper weights. Many building codes prescribe the minimum weights for only a few building materials, and in other instances no guide whatsoever is furnished on this subject. In some cases, the codes are drawn up so as to leave the question of what weights to use to the discretion of the building official, without providing any authoritative guide. This practice, as well as the use of incomplete lists, has been subjected to much criticism. The solution chosen has been to present, in this commentary, an extended list that will be useful to designer and official alike. However, special cases will unavoidably arise, and authority is therefore granted in the standard for the building official to deal with them.

For ease of computation, most values are given in terms of pounds per square foot, psf (kilonewtons per square meter, kN/m^2) of given thickness in Tables C3.1-1a and C3.1-1b. Pounds-per-cubic-foot, lb/ft^3 (kN/m^3), values, consistent with the pounds-per-square foot psf (kilonewtons per square meter, kN/m^2) values, are also presented in some cases in Table C3.1-2. Some constructions for which a single figure is given actually have a considerable range in weight. The average figure given is suitable for general use, but when there is reason to suspect a considerable deviation from this, the actual weight should be determined.

Engineers, architects, and building owners are advised to consider factors that result in differences between actual and calculated loads.

Engineers and architects cannot be responsible for circumstances beyond their control. Experience has shown, however, that conditions are encountered that, if not considered in design, may reduce the future utility of a building or reduce its margin of safety. Among them are

- *Dead loads*. There have been numerous instances in which the actual weights of members and construction materials have exceeded the values used in design. Care is advised in the use of tabular values. Also, allowances should be made for such factors as the influence of formwork and support deflections on the actual thickness of a concrete slab of prescribed nominal thickness.
- *Future installations*. Allowance should be made for the weight of future wearing or protective surfaces where there is a good possibility that such may be applied. Special consideration should be given to the likely types and position of partitions, as insufficient provision for partitioning may reduce the future utility of the building.

Attention is directed also to the possibility of temporary changes in the use of a building, as in the case of clearing a dormitory for a dance or other recreational purpose.

C3.1.3 Weight of Fixed Service Equipment Fixed service equipment includes but is not limited to plumbing stacks and risers; electrical feeders; heating, ventilating, and air conditioning systems; and process equipment such as vessels, tanks, piping, and cable trays. Both the empty weight of equipment and the maximum weight of contents are treated as dead load.

Section 1.3.6 indicates that when resistance to overturning, sliding, and uplift forces is provided by dead load, the dead load shall be taken as the minimum dead load likely to be in place. Therefore, liquid contents and movable trays shall not be used to resist these forces unless they are the source of the forces. For example, the liquid in a tank contributes to the seismic mass of the tank and therefore can be used to resist the seismic uplift; however, the weight of the liquid cannot be used to resist overturning, sliding, or uplift from wind loads because the liquid may not be present during the wind event.

C3.1.4 Vegetative and Landscaped Roofs Landscaping elements, such as soil, plants, and drainage layer materials, and hardscaping elements, such as walkways, fences, and walls, are intended to remain in place and are therefore considered dead loads. While the weight of hardscaping materials does not fluctuate, the weight of soil and drainage layer materials used to support vegetative growth is subject to significant variation because of its ability to absorb and retain water. Where the weight is additive to other loads, the dead load should be computed assuming full saturation of soil and drainage layer materials. Where the weight acts to counteract uplift forces, the dead load should be computed assuming dry unit weight of the soil and dry drainage layer materials.

Vegetative and landscaped roof areas may be able to retain more water than the condition where the soil and drainage layer materials are fully saturated. The water may result from precipitation or from irrigation of the vegetation. This additional amount of water should be considered rain load in accordance with Chapter 8 or snow load in accordance with Chapter 7 as applicable.

C3.1.5 Solar Panels This section clarifies that solar panel-related loads, including ballasted systems that are not permanently attached, shall be considered as dead loads for all load combinations specified in Chapter 2.

C3.2 SOIL LOADS AND HYDROSTATIC PRESSURE

C3.2.1 Lateral Pressures Table 3.2-1 includes high earth pressures, 85 pcf ($13.36\ kN/m^3$) or more, to show that certain soils are poor backfill material. In addition, when wall horizontal

movement is restricted at the top, the earth pressure is increased from active pressure toward earth pressure at rest, resulting in 60 pcf (9.43 kN/m^3) for granular soils and 100 pcf (15.71 kN/m^3) for silt and clay type soils (Terzaghi and Peck 1967). The exception permits active pressure to be used for shallow foundation walls supporting flexible floor diaphragms such as wood-framed floors and cold-formed steel joists without a cast-in-place concrete floor attached.

Expansive soils exist in many regions of the United States and may cause serious damage to foundation walls unless special design considerations are provided. Expansive soils should not be used as backfill because they can exert very high pressures against walls. Special soil testing is required to determine the magnitude of these pressures. It is preferable to excavate expansive soil and backfill with nonexpansive, freely draining sands or gravels. The excavated back slope adjacent to the wall should be

@seismicisolation

no steeper than 45 degrees from the horizontal to minimize the transmission of swelling pressure from the expansive soil through the new backfill. Other special details are recommended, such as a cap of nonpervious soil on top of the backfill and provision of foundation drains. Refer to current reference books on geotechnical engineering for guidance.

C3.2.2 Uplift Loads on Floors and Foundations If expansive soils are present under floors or footings, large pressures can be exerted and must be resisted by special design. Alternatively, the expansive soil can be removed and replaced with nonexpansive material. A geotechnical engineer should make recommendations in these situations.

C3.3 ALTERNATIVE METHOD FOR LOADS FROM WATER IN SOIL

Prior to the 2022 edition, the standard did not define hazard levels for groundwater in soil. The probability levels now defined for maximum and minimum levels of groundwater correspond, in round numbers, to mean recurrence intervals of 400, 800, 1,700, and 3,300 years for the four risk categories. These are similar, but not identical to the intervals of 300, 750, 3,000, and 10,000 years specified for hydraulic structures by the US Army Corps of Engineers (USACE). The hazard levels selected for ASCE 7 are not the same as used by the USACE, because the USACE uses a different classification of risks for hydraulic structures than the risk classification used in ASCE 7. Site specific information is required to establish these groundwater levels, although conservative assumptions can be made in practice, such as setting the maximum groundwater level at the ground surface where not in a flood zone. Ground water pressure in a flood zone may or may not be correlated with flood elevation depending on many factors, including the nature of the soil and the duration of flood. Professionals responsible for establishing groundwater levels have various resources, including historical data from the USGS National Water Information System (wells monitoring known aquifers), flood zone maps, and local geological and hydrological information. Information sources will vary from region to region and site to site. The difficulty in obtaining usable data is a primary reason this method is included as an elective alternate, rather than the only approved method.

CHAPTER C4
LIVE LOADS

C4.3 UNIFORMLY DISTRIBUTED LIVE LOADS

C4.3.1 Required Live Loads A selected list of loads for occupancies and uses more commonly encountered is given in Section 4.3.1, and the Authority Having Jurisdiction should approve on occupancies not mentioned. Tables C4.3-1 and C4.3-2 are offered as a guide in the exercise of such authority.

In selecting the occupancy and use for the design of a building or a structure, the building owner should consider the possibility of later changes of occupancy involving loads heavier than originally contemplated. The lighter loading appropriate to the first occupancy should not necessarily be selected. The building owner should ensure that a live load greater than that for which a floor or roof is approved by the Authority Having Jurisdiction is not placed, or caused or permitted to be placed, on any floor or roof of a building or other structure.

To solicit specific informed opinion regarding the design loads in Table 4.3-1, a panel of 25 distinguished structural engineers was selected. A Delphi (Corotis et al. 1981) was conducted with this panel in which design values and supporting reasons were requested for each occupancy type. The information was summarized and recirculated back to the panel members for a second round of responses. Those occupancies for which previous design loads were reaffirmed and those for which there was consensus for change were included.

It is well known that the floor loads measured in a live load survey usually are well below present design values (Peir and Cornell 1973, McGuire and Cornell 1974, Sentler 1975, Ellingwood and Culver 1977). However, buildings must be designed to resist the maximum loads they are likely to be subjected to during some reference period T, frequently taken as 50 years. Table C4.3-2 briefly summarizes how load survey data are combined with a theoretical analysis of the loading for some common occupancy types and illustrates how a design load might be selected for an occupancy not specified in Table 4.3-1 (Chalk and Corotis 1980). The floor load normally present for the intended functions of a given occupancy is referred to as the sustained load. This load is modeled as constant until a change in tenant or occupancy type occurs. A live load survey provides the statistics of the sustained load. Table C4.3-2 gives the mean, m_s, and standard deviation, σ_s, for particular reference areas. In addition to the sustained load, a building is likely to be subjected to a number of relatively short-duration, high-intensity, extraordinary, or transient loading events (caused by crowding in special or emergency circumstances, concentrations during remodeling, and the like). Limited survey information and theoretical considerations lead to the means, m_t, and standard deviations, σ_t, of single transient loads shown in Table C4.3-2.

Combination of the sustained load and transient load processes, with due regard for the probabilities of occurrence, leads to statistics of the maximum total load during a specified reference period. The statistics of the maximum total load depend on the average duration of an individual tenancy, τ, the mean rate of occurrence of the transient load, ν_e, and the reference period, T. Mean values are given in Table C4.3-2. The mean of the maximum load is similar, in most cases, to Table 4.3-1 values of minimum uniformly distributed live loads and, in general, is a suitable design value.

For library stack rooms, the 150 psf (7.18 kN/m^2) uniform live load specified in Table 4.3-1 is intended to cover the range of ordinary library shelving which is described in Section 4.13. The 150 psf (7.18 kN/m^2) floor loading is also applicable to typical file cabinet installations, provided that the 36 in. (0.92 m) minimum aisle width is maintained. Five-drawer lateral or conventional file cabinets, even with two levels of bookshelves stacked above them, are unlikely to exceed the 150 psf (7.18 kN/m^2) average floor loading unless all drawers and shelves are filled to capacity with maximum density paper. Such a condition is essentially an upper bound for which the normal load factors and safety factors applied to the 150 psf (7.18 kN/m^2) criterion should still provide a safe design.

The 50 psf (2.40 kN/m^2) live load for theater follow spot, projection, and control rooms considers the use of typical theater equipment such as projectors, spotlights, and equipment to control the sound, lighting, and HVAC within the theater. When these rooms are used for storage, the live load used should account for the actual conditions.

For the 2010 version of the standard, the provision in the live load table for "Marquees" with its distributed load requirement of 75 psf (3.59 kN/m^2) was removed, along with "Roofs used for promenade purposes" and its 60 psf (2.87 kN/m^2) loading. Both *marquee* and *promenade* are considered archaic terms that are not used elsewhere in the standard or in building codes, with the exception of the listings in the live load tables. "Promenade purposes" is essentially an assembly use and is more clearly identified as such.

"Marquee" has not been defined in this standard but has been defined in building codes as a roofed structure that projects into a public right of way. However, the relationship between a structure and a right of way does not control loads that are applied to a structure. The marquee should therefore be designed with all of the loads appropriate for a roofed structure. If the arrangement of the structure is such that it invites additional occupant loading (e.g., there is window access that might invite loading for spectators of a parade), balcony loading should be considered for the design.

Balconies and decks are recognized as often having distinctly different loading patterns than most interior rooms. They are often subjected to concentrated live loads from people congregating along the edge of the structure (e.g., for viewing vantage points). This loading condition is acknowledged in Table 4.3-1 as

@seismicisolation

Table C4.3-1. Minimum Uniformly Distributed Live Loads.

Occupancy or Use	Live Load, psf (kN/m^2)	Occupancy or Use	Live Load, psf (kN/m^2)
Air conditioning (machine space)	200 (9.58)[a]	Laboratories, scientific	100 (4.79)

[b] Duration of average sustained load occupancy.
[c] Mean rate of occurrence of transient load.
[d] Reference period.

@seismicisolation

an increase of the live load for the area served, up to the point of satisfying the loading requirement for most assembly occupancies. As always, the designer should be aware of potential unusual loading patterns in the structure that are not covered by these minimum standards.

The minimum live loads applicable to roofs with vegetative and landscaped areas are dependent upon the use of the roof area. The 20 psf (0.96 kN/m^2) live load for unoccupied areas is the same load as for typical roof areas and is intended to represent the loads caused by maintenance activities and small decorative appurtenances. The 100 psf (4.79 kN/m^2) live load for roof assembly areas is the same as prescribed for interior building areas because the potential for a dense grouping of occupants is similar. Other occupancies within green roof areas should have the same minimum live load as specified in Table 4.3-1 for that occupancy. Soil and walkways, fences, walls, and other hardscaping features are considered dead loads in accordance with Section 3.1.4.

The public restroom uniform live load in Table 4.3-1 applies to restrooms for publicly accessible spaces. Public restrooms should be designed for the live load associated with the occupancy it serves, with an upper limit of 60 psf (2.87 kN/m^2). The upper limit recognizes that the fixtures within restrooms limit the space available for a dense grouping of occupants.

C4.3.2 Provision for Partitions Partition load provisions have been included in the standard since the first edition in 1988, however the 2005 edition was the first edition to provide a minimum value for the partition load. Historically, a value of 20 psf (0.96 kN/m^2) has been required by building codes. The 20 psf (0.96 kN/m^2) value, however, was typically specified as a dead load.

The live load value of 15 psf (0.72 kN/m^2) with a load factor of 1.6 gives the same structural demand as a dead load value of 20 psf (0.96 kN/m^2) with a 1.2 load factor. When partitions were considered as dead load, the partition load would counteract potential uplift conditions, such as the backspan of a cantilevered member or in the overturning of the structure due to lateral loads. As a live load, the partition load is excluded from the uplift load combinations and is also subject to the partial loading provisions in Section 4.3.

Assuming that a normal partition would be a stud wall with 0.5 in. (13 mm) gypsum board on each side, 8 psf (0.38 kN/m^2) per Table C3.1-1, and 10 ft (3.05 m) high, the wall load on the floor would be 80 psf (1.16 kN/m). If the partitions are spaced throughout the floor area creating rooms on a grid 10 ft (3.05 m) on center, which would be an extremely dense spacing over a whole bay, the average distributed load would be 16 psf (0.77 kN/m^2). A design value of 15 psf (0.72 kN/m^2) is judged to be reasonable in that the partitions are not likely to be spaced this closely over large areas. Designers should consider a larger design load for partitions if taller wall heights, heavier walls, or a higher density of partitions is anticipated.

The nature of the distribution of partitions is fundamentally different from office live loads, so the partition live load is not reducible in the design for gravity loads. Another difference with ordinary live loads is that the partition load is both semipermanent and firmly attached to the structure. Therefore, the partition weight is required to be considered as a part of the effective seismic weight for seismic design (see Chapter 12).

C4.3.3 Partial Loading Uniform live loads applied over only a portion of a structure or a member can produce greater forces than when uniform live loads are applied over the full length of the structure or member.

Partial-length loads on a simple beam or truss produce higher shear on a portion of the span than a full-length load. "Checkerboard" load patterns applied to multistory, multipanel bents, frames, and continuous members produce higher positive moments than loads applied to all spans, whereas loads on either side of a support produce greater negative moments. Loads on the half span of arches and domes or on the two central quarters can be critical.

Cantilevers must not rely on a possible live load on the back span for equilibrium.

C4.3.3.1 Partial Loading of Roofs All probable load patterns should be considered uniform for roof live loads that are reduced to less than 20 psf (0.96 kN/m^2) using Section 4.8. Where the full value of the roof live load (L_r) is used without reduction, it is considered that there is a low probability that the loads from maintenance workers, equipment, and material could occur in a patterned arrangement. Where a uniform roof live load is caused by occupancy, partial or pattern loading should be considered regardless of the magnitude of the uniform load.

C4.3.4 Interior Walls and Partitions Interior walls and partitions are subjected to lateral loads from occupants, occasional impact from moving furniture or equipment, and from pressurization from heating, ventilating and air-conditioning (HVAC) systems. The 5 psf (0.24 kN/m^2) horizontal load is judged to be reasonable to provide for out-of-plane strength and stability. Interior walls and partitions that are subjected to larger lateral loads should be designed for those loads.

C4.4 CONCENTRATED LIVE LOADS

The provision in Table 4.3-1 regarding concentrated loads supported by roof trusses or other primary roof members is intended to provide for a common situation for which specific requirements are generally lacking.

Primary roof members are main structural members such as roof trusses, girders, and frames, which are exposed to a work floor below, where the failure of such a primary member resulting from their use as attachment points for lifting or hoisting loads could lead to the collapse of the roof. Single roof purlins or rafters (where there are multiple such members placed side by side at some reasonably small center-to-center spacing, and where the failure of a single such member would not lead to the collapse of the roof) are not considered to be primary roof members.

C4.5 LOADS ON HANDRAIL, GUARD, GRAB BAR, AND VEHICLE BARRIER SYSTEMS, AND ON SHOWER SEATS AND FIXED LADDERS

C4.5.1 Handrail and Guard Systems Loads that can be expected to occur on handrail and guard systems are highly dependent on the use and occupancy of the protected area. The single concentrated load applied on the handrail or top rail represents load from one person or object, or a small number of people.

C4.5.1.1 Uniform Load. The uniform load represents distributed loads such as from a group of people. For cases in which extreme loads can be anticipated, such as long, straight runs of guard systems against which crowds can surge, appropriate increases in loading should be considered. There are three exceptions that allow the uniform load to not be applied, such as when handrail and guard systems are located in areas not typically open to the general public.

@seismicisolation
@seismicisolation

C4.5.2 Grab Bar Systems and Shower Seats The specified concentrated live load provides for the normal anticipated use of grab bars and shower seats. Shower seats include built-in seats and seats that are removable but secured to the shower or tub. The specified concentrated live load provides consistency with ICC/ANSI A117.1, *Accessible and Usable Buildings and Facilities* (2017). However, while grab bars and shower seats are commonly provided for use by persons with physical disabilities, they shall be designed to resist the concentrated load whenever they are provided.

C4.5.3 Vehicle Barrier Systems Vehicle barrier systems may be subjected to horizontal loads from moving vehicles. These horizontal loads may be applied normal to the plane of the barrier system, parallel to the plane of the barrier system, or at any intermediate angle. Loads in garages accommodating trucks and buses may be obtained from the provisions contained in AASHTO *LRFD Bridge Design Specifications* (2014/2015).

C4.5.4 Fixed Ladders This provision was introduced to the standard in 1998 and is consistent with the provisions for stairs.

Side rail extensions of fixed ladders are often flexible and weak in the lateral direction. The Occupational Safety and Health Administration (OSHA 2014a) requires side rail extensions, only with specific geometric requirements. The load provided was introduced to the standard in 1998 and has been determined on the basis of a 250 lb (1.11 kN) person standing on a rung of the ladder and accounting for reasonable angles of pull on the rail extension.

C4.6 IMPACT LOADS

Grandstands, stadiums, and similar assembly structures may be subjected to loads caused by crowds swaying in unison, jumping to their feet, or stomping. Designers are cautioned that the possibility of such loads should be considered.

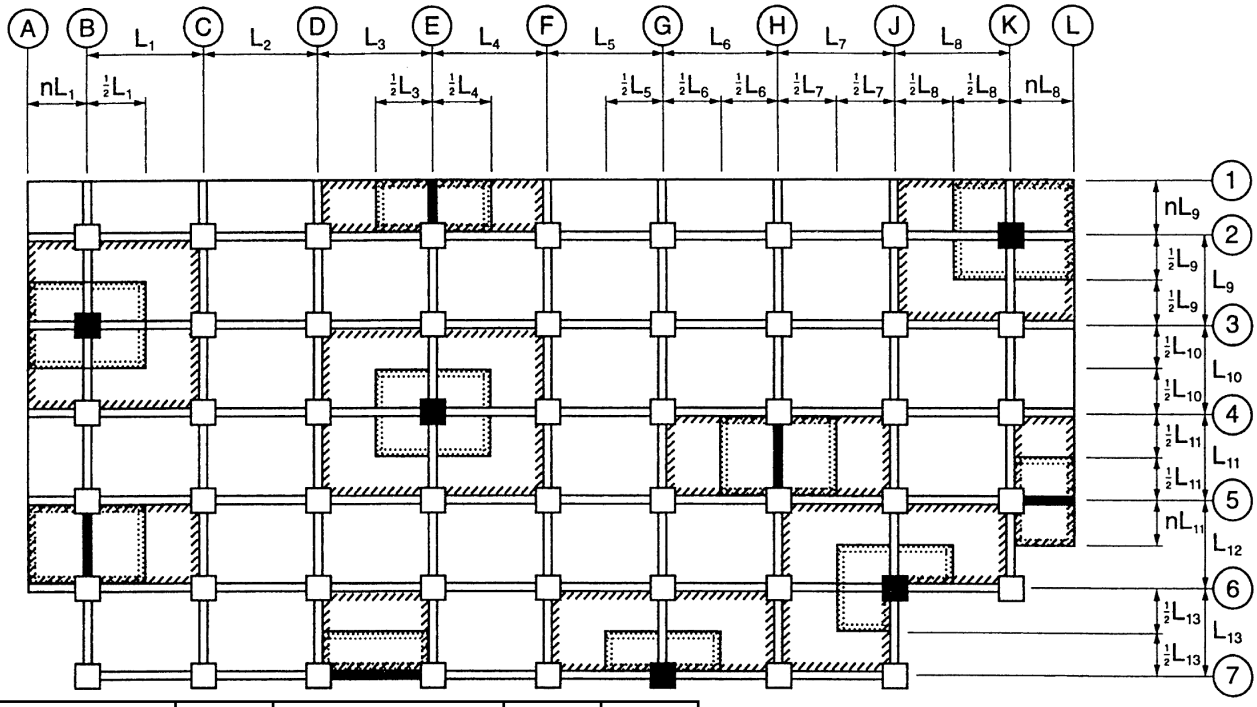
Elevator loads are changed in the standard from a direct 100% impact factor to a reference to ASME A17.1 (2016). The provisions in ASME A17.1 include the 100% impact factor, along with deflection limits on the applicable elements.

C4.6.4 Elements Supporting Hoists for Façade Access and Building Maintenance Equipment The Occupational Safety and Health Administration (OSHA) requires that façade access platforms that are used for building maintenance meet the requirements of Standard 1910.66, *Powered Platforms for Building Maintenance* (OSHA 2014b). OSHA requires that building anchors and components be capable of sustaining without failure a load of at least four times the rated load of the hoist (i.e., the maximum anticipated load or total weight of the suspended platform plus occupants and equipment) applied or transmitted to the components and anchors. A design live load of 2.5 times the rated load, when combined with a live load factor of 1.6, results in a total factored load of 4.0 times the rated load, which matches OSHA's requirements. It should also be noted that when using allowable stress design (ASD), 2.5 times the rated load will result in a comparable design when a safety factor of 1.6 is used in determining the allowable stresses. This load requirement is not statistically based but is intended by OSHA to address accidental hang-up-and-fall scenarios as well as starting and stopping forces that the platforms experience on a day-to-day basis. It also provides a small margin of safety relative to situations where a suspended platform gets hung up on a façade while ascending, allowing the hoists to apply large forces on the supporting elements. OSHA permits hoists to generate in-service forces up to three times their rated loads. These loads should be applied in the same direction(s) as they are expected to occur.

OSHA (2014c) provisions (CFR 1926.451) related to "construction" activities also require supporting equipment to be able to carry at least 1.5 times the stall load of the supported hoist. Since OSHA defines "construction" rather broadly (it includes activities such as painting and hanging signs), most equipment is used for "construction" work, which means that it must have the strength required by OSHA construction provisions. The stall load times the live load factor of 1.6 slightly exceeds the OSHA 1.5 times the stall load requirement.

C4.6.5 Fall Arrest, Lifeline, and Rope Descent System Anchorages OSHA requires that anchorages that support fall arrest lines, lifelines, and rope descent systems be capable of sustaining without failure an ultimate load of 5,000 lb (22.2 kN) for each attached person. Using a design live load of 3,100 lb (13.8 kN), when combined with a live load factor of 1.6, results in a total factored load of 4,960 lb (22.1 kN), which essentially matches OSHA's requirements for lifeline anchorages. It should also be noted that when using Allowable Stress Design (ASD), a design live load of 3,100 lb (13.8 kN) results in a comparable design when a safety factor of 1.6 is used in determining the allowable stresses. This lifeline load is intended by OSHA to address the fall arrest loads that can and do reasonably occur in typical lanyards for body harnesses, which are highly variable.

When a fall arrest load is applied perpendicular to the length of a horizontal lifeline, much larger loads can develop at the end anchorages due to the geometry of the horizontal cable; it is important that these increased forces be considered in the design of the anchorages and their supports.



C4.7 REDUCTION IN UNIFORM LIVE LOADS

C4.7.1 General The concept of, and methods for, determining member live load reductions as a function of a loaded member's influence area, A_I, was first introduced into this standard in 1982 and was the first such change since the concept of live load reduction was introduced more than 40 years ago. The revised formula is a result of more extensive survey data and theoretical analysis (Harris et al. 1981). The change in format to a reduction multiplier results in a formula that is simple and more convenient to use. The use of influence area, now defined as a function of the tributary area, A_T, in a single equation has been shown to give more consistent reliability for the various structural effects. The influence area is defined as that floor area over which the influence surface for structural effects is significantly different from zero.

The factor K_{LL} is the ratio of the influence area (A_I) of a member to its tributary area (A_T), that is, $K_{LL} = A_I/A_T$, and is used to better define the influence area of a member as a function of its tributary area. Figure C4.7-1 illustrates typical influence areas and tributary areas for a structure with regular bay spacings. Table 4.7-1 has established K_{LL} values (derived from calculated K_{LL} values) to be used in Equation (4.7-1) for a variety of structural members and configurations. Calculated K_{LL} values vary for column and beam members that have adjacent cantilever construction, as is shown in Figure C4.7-1, and the Table 4.7-1 values have been set for these cases to result in live load reductions that are slightly conservative. For unusual shapes, the concept of significant influence effect should be applied.

An example of a member without provisions for continuous shear transfer normal to its span would be a precast T-beam or double-T beam that may have an expansion joint along one or

@seismicisolation
@seismicisolation

Element	Actual K_{LL} Members w/o Cantilevers	Actual K_{LL} Members w/ Cantilevers			K_{LL} (Table 4.7.1)	Example Member (Fig.C4.7-1)
		n = 0	n = 0.5	n = 1.0		
Interior Columns	4	-	-	-	4	E4
Exterior Columns w/o cantilevers	4	-	-	-	4	G7, J6
Edge Columns w/ cantilevers	-	4	3	2.67	3	B3
Corner Columns w/ cantilevers	-	4	2.25	1.78	2	K2
Edge Beams w/o cantilever slabs	2	-	-	-	2	D7 - E7
Interor Beams	2	-	-	-	2	H4 - H5
Edge Beams w/ cantilever slabs	-	2	1.5	1.33	1	B5 - B6
Cantilever Beams w/o cantilever slabs	2	-	-	-	1	E1 - E2
Cantilever Beams w/ cantilever slabs	-	2*	1.5*	1.33*	1	K5 - L5

* The value of n for member K5-L5 is used to calculate the distance nL_{11}

Figure C4.7-1. Typical tributary and influence areas.

both flanges or that may have only intermittent weld tabs along the edges of the flanges. Such members do not have the ability to share loads located within their tributary areas with adjacent members, thus resulting in $K_{LL} = 1$ for these types of members. Reductions are permissible for two-way slabs and for beams, but care should be taken in defining the appropriate influence area. For multiple floors, areas for members supporting more than one floor are summed.

The formula provides a continuous transition from unreduced to reduced loads. The smallest allowed value of the reduction multiplier is 0.4 (providing a maximum 60% reduction), but there is a minimum of 0.5 (providing a 50% reduction) for members with a contributory load from just one floor.

C4.7.3 Heavy Live Loads In the case of occupancies involving relatively heavy basic live loads, such as storage buildings, several adjacent floor panels may be fully loaded. However, data obtained in actual buildings indicate that rarely is any story loaded with an average actual live load of more than 80% of the average rated live load. It appears that the basic live load should not be reduced for the floor-and-beam design, but that it could be reduced by up to 20% for the design of members supporting more than one floor. Accordingly, this principle has been incorporated in the recommended requirement.

C4.7.4 Passenger Vehicle Garages Unlike live loads in office and residential buildings, which are generally spatially random, parking garage loads are caused by vehicles parked in regular patterns, and the garages are often full. The rationale behind the reduction according to area for other live loads, therefore, does not apply. A load survey of vehicle weights was conducted at nine commercial parking garages in four cities of different sizes (Wen and Yeo 2001). Statistical analyses of the maximum load effects on beams and columns caused by vehicle loads over the garage's life were carried out using the survey results. Dynamic effects on the deck caused by vehicle motions, and on the ramp caused by impact, were investigated. The equivalent uniformly distributed loads (EUDL) that would produce the lifetime maximum column axial force and midspan beam bending moment are conservatively estimated at 34.8 psf (1.67 kN/m^2). The EUDL is not sensitive to bay-size variation. In view of the possible impact of very heavy vehicles in the future such as sport utility vehicles, however, a design load of 40 psf (1.95 kn/m^2) is recommended with no allowance for reduction according to bay area.

@seismicisolation

Compared with the design live load of 50 psf (2.40 kN/m^2) given in previous editions of the standard, the design load contained herein represents a 20% reduction, but it is still 33% higher than the 30 psf (1.44 kn/m^2) one would obtain were an area-based reduction to be applied to the 50 psf (2.40 kN/m^2) value for large bays as allowed in most standards. Also, the variability of the maximum parking garage load effect is found to be small, with a coefficient of variation less than 5% in comparison with 20% to 30% for most other live loads. The implication is that when a live load factor of 1.6 is used in design, additional conservatism is built into it such that the recommended value would also be sufficiently conservative for special-purpose parking (e.g., valet parking) where vehicles may be more densely parked, causing a higher load effect. Therefore, the 50 psf (2.40 kN/m^2) design value was felt to be overly conservative, and it can be reduced to 40 psf (1.95 kn/m^2) without sacrificing structural integrity.

C4.7.6 Limitations on One-Way Slabs One-way slabs behave in a manner similar to two-way slabs but do not benefit from having a higher redundancy that results from two-way action. For this reason, it is appropriate to allow a live load reduction for one-way slabs but restrict the tributary area, A_T, to an area that is the product of the slab span times a width normal to the span not greater than 1.5 times the span (thus resulting in an area with an aspect ratio of 1.5). For one-way slabs with aspect ratios greater than 1.5, the effect is to give a somewhat higher live load (where a reduction has been allowed) than for two-way slabs with the same ratio.

Members, such as hollow-core slabs, that have grouted continuous shear keys along their edges and span in one direction only, are considered as one-way slabs for live load reduction, even though they may have continuous shear transfer normal to their spans.

C4.8 REDUCTION IN ROOF LIVE LOADS

C4.8.2 Ordinary Roofs, Awnings, and Canopies The values specified in Equation (4.8-1) that act vertically on the projected area have been selected as minimum roof live loads, even in localities where little or no snowfall occurs. This is because it is considered necessary to provide for occasional loading caused by the presence of workers and materials during repair operations.

C4.8.3 Occupiable Roofs Designers should consider any additional dead loads that may be imposed by saturated landscaping materials in addition to the live load required in Table 4.3-1. Occupancy-related loads on roofs are live loads (L) normally associated with the design of floors rather than roof live loads (L_r) and may be reduced in accordance with the provisions for live loads in Section 4.7 rather than Section 4.8.

C4.9 CRANE LOADS

All support components of moving bridge cranes and monorail cranes, including runway beams, brackets, bracing, and connections, shall be designed to support the maximum wheel load of the crane and the vertical impact, lateral, and longitudinal forces induced by the moving crane. Also, the runway beams shall be designed for crane stop forces. The methods for determining these loads vary depending on the type of crane system, support, and service class. CMAA (2015a, b), MMA (2016), and MBMA (2018) describe types of bridge cranes and monorail cranes, including top running bridge cranes with top running trolley, underhung bridge cranes, and underhung monorail cranes. The bridge crane service class descriptions are based on those given in CMAA (2015a), which are used by crane manufacturers to efficiently design and manufacture cranes for each installation. Designers of crane runways and connections of runway beams to columns also consider fatigue, which is associated with crane service class. AIST (2003) gives more stringent requirements for crane runway designs that are more appropriate for higher capacity or higher speed crane systems with service class E or F.

C4.10 GARAGES AND VEHICULAR FLOOR LOADS

Buildings and structures that support vehicle loads include both structures where vehicles enter the structure, such as parking garages, convention centers, manufacturing and storage buildings, and the receiving areas of retail and large office buildings, as well as structures where vehicles travel on top of the structure, such as plaza decks and sidewalks over below-grade spaces.

C4.10.1 Passenger Vehicle Garages In view of the large load effect produced by a single heavy vehicle [up to 10,000 lb (44.48 kN)], the previous concentrated load of 2,000 lb (8.90 kN) was increased to 3,000 lb (13.34 kN) in the 2002 edition of the standard. For passenger vehicle garages, the concentrated load of 3,000 lb (13.34 kN) acting on an area of 4.5 in. × 4.5 in. (114 mm × 114 mm) represents the load caused by a jack when changing tires on a single heavy vehicle [up to 10,000 lb (44.48 kN)]. See Section C4.7.4 for commentary regarding the passenger vehicle garage uniform live load.

C4.10.2 Truck and Bus Garages The passenger vehicle loads provided in Section 4.10.1 of this standard are limited to vehicles such as cars, sport utility vehicles, minivans, and pickup trucks. For heavier trucks and buses, the vehicular live loads in the AASHTO LRFD Bridge Design Specifications (AASHTO) are to be applied. The AASHTO provisions for fatigue and dynamic load allowance are not required to be applied as the vehicle speeds in garages and vehicle storage areas are much lower than typical highway speeds.

The exception to the requirement to use the AASHTO vehicle loads allows the actual vehicle weights to be used with the approval of the Authority Having Jurisdiction. This could be applied for example in garages used for vehicles such as garbage trucks, armored trucks, and delivery trucks that are heavier than passenger vehicles but lighter than the highway semitrailer and triple-axle trucks represented by the AASHTO design truck.

C4.10.3 Sidewalks, Vehicular Driveways, and Yards Subject to Trucking The large uniform and concentrated load specified for these areas have been historically used to design city sidewalk areas over basements and vaults that can be subject to trucks driving up on the sidewalk and parking to unload.

C4.10.4 Emergency Vehicle Loads Examples of structures that are accessible to emergency vehicles include parking garages and at-grade areas such as plaza decks and parking lots over underground structures. Fire trucks and ambulances are likely to enter these areas when responding to emergencies, therefore they are required to be designed for the vehicle loads unless access is physically restricted. Moveable physical barriers are not considered to physically restrict access as they may allow emergency vehicles on the structure if the barriers are not present when the emergency occurs or if the barriers swing out of the way for the emergency vehicle.

The emergency vehicle live loads are permitted to be either the operating loads of the vehicles in the local jurisdiction or the AASHTO design truck and design tandem live loads. The operating loads are required to be obtained from the Authority Having Jurisdiction (AHJ) as they have the most knowledge of

@seismicisolation
@seismicisolation

emergency vehicles in their jurisdiction and their mutual aid partner jurisdictions. The AHJ may need to consult with the vehicle manufacturer to determine the weight and outrigger loads if this information has not been previously documented. Operating loads include the vehicle weight, equipment weight, and, if present, stored water weight. The wheel and outrigger loads need to account for the distribution of the weight, the wheel and outrigger pad contact area and spacing, and the operation of integral ladders and aerial platforms when present. Outrigger reactions can be significant as industry standards permit ratings of up to 60,000 lb (266.9 kN).

C4.11 HELIPAD LOADS

C4.11.1 General Helipad provisions were added to the standard in 2010. For the standard, the term *helipads* is used to refer specifically to the structural surface. In building codes and other references, different terminology may be used when describing helipads, e.g., heliports, helistops, but the distinctions between these are not relevant to the structural loading issue addressed in ASCE 7.

Although these structures are intended to be specifically kept clear of non-helicopter occupant loads on the landing and taxi areas, the uniform load requirement is a minimum to ensure a degree of substantial construction and the potential to resist the effects of unusual events.

Additional information on helipad design can be found in Annex 14 to the *Convention on International Civil Aviation, Aerodromes, Vol. 2* (ICAO 2013).

C4.11.2 Concentrated Helicopter Loads Concentrated loads applied separately from the distributed loads are intended to cover the primary helicopter loads. The designer should always consider the geometry of the design basis helicopter for applying the design loads. A factor of 1.5 is used to address impact loads (two single concentrated loads of 0.75 times the maximum takeoff weight) to account for a hard landing with many kinds of landing gear. The designer should be aware that some helicopter configurations, particularly those with rigid landing gear, could result in substantially higher impact factors that should be considered.

The 3,000 lb (13.34 kN) concentrated load is intended to cover maintenance activities, similar to the jack load for a parking garage.

C4.13 LIBRARY STACK ROOMS

Where library shelving installation does not fall within the parameter limits that are specified in Section 4.13 and Table 4.3-1, the design should account for the actual conditions. For example, the floor loading for storage of medical X-ray film may easily exceed 200 psf (9.58 kN/m^2), mainly because of the increased depth of the shelves. Mobile library shelving that rolls on rails should also be designed to meet the actual requirements of the specific installation, which may easily exceed 300 psf (14.4 kN/m^2). The rail support locations and deflection limits should be considered in the design, and the engineer should work closely with the system manufacturer to provide a serviceable structure.

C4.14 SEATING FOR ASSEMBLY USES

The lateral loads apply to "stadiums and arenas" and to "bleachers, folding and telescopic seating, and grandstands." However, it does not apply to "gymnasiums." Consideration should be given to treating gymnasium balconies that have stepped floors for seating as arenas, and requiring the appropriate swaying forces.

C4.17 SOLAR PANEL LOADS

C4.17.1 Roof Loads at Solar Panels These provisions were added to the 2016 edition of the standard to address the installation of rooftop solar panels consistent with current practices (Blaney and LaPlante 2013). These provisions allow the offset of roof live load where the space below the solar panel is considered inaccessible. The dimension of 24 in. (610 mm) was chosen as the clear vertical distance as it is consistent with existing published requirements for solar panel systems and is also a typical minimum height permitted for access into or out of spaces.

C4.17.3 Open-Grid Roof Structures Supporting Solar Panels This section reduces the uniform roof live load for building structures such as carports and shade structures, which do not include roof deck or sheathing, to the value of the minimum uniform roof live load permitted by Section 4.8.2. The concentrated roof live load requirement in Table 4.3-1 is not modified by this section.

@seismicisolation
@seismicisolation

CHAPTER C5
FLOOD LOADS

C5.1 GENERAL

This section presents information for the design of buildings and other structures in areas prone to flooding. Design professionals should be aware that there are important differences between flood characteristics, flood loads, and flood effects in riverine and coastal areas (e.g., the potential for wave effects is much greater in coastal areas, the depth and duration of flooding can be much greater in riverine areas, the direction of flow in riverine areas tends to be more predictable, and the nature and amount of flood-borne debris varies between riverine and coastal areas).

Much of the impetus for flood-resistant design has come about from the federal government sponsored initiatives of flood-damage mitigation and flood insurance, both through the work of the USACE and the National Flood Insurance Program (NFIP). The NFIP is based on an agreement between the federal government and participating communities that have been identified as being flood prone. The Federal Emergency Management Agency (FEMA), through the Federal Insurance and Mitigation Administration (FIMA), makes flood insurance available to the residents of communities provided that the community adopts and enforces adequate floodplain management regulations that meet the minimum FIMA requirements. Included in the NFIP requirements, found under Title 44 of the US Code of Federal Regulations (FEMA 1999b), are minimum building design and construction standards for buildings and other structures located in special flood hazard areas (SFHAs).

Special flood hazard areas are those identified by FEMA as being subject to inundation during the 100-year flood. SFHAs are shown on flood insurance rate maps (FIRMs), which are produced for flood-prone communities. SFHAs are identified on FIRMs as zones A, A1-30, AE, AR, AO, and AH, and in coastal high hazard areas as V1-30, V, and VE. The SFHA is the area in which communities must enforce NFIP-compliant, flood-damage-resistant design and construction practices.

Before designing a structure in a flood-prone area, design professionals should contact the local building official to determine if the site in question is located in an SFHA or other flood-prone area that is regulated under the community's floodplain management regulations. If the proposed structure is located within the regulatory floodplain, local building officials can explain the regulatory requirements.

Answers to specific questions on flood-resistant design and construction practices may be directed to the mitigation division of each of FEMA's regional offices, which are available to assist design professionals.

C5.2 DEFINITIONS

Three new concepts were added with ASCE 7-98. First, the concept of the design flood was introduced. The design flood will, at a minimum, be equivalent to the flood having a 1% chance of being equaled or exceeded in any given year (i.e., the base flood or 100-year flood, which served as the load basis in ASCE 7-95). In some instances, the design flood may exceed the base flood in elevation or spatial extent; this excess will occur where a community has designated a greater flood (lower frequency, higher return period) as the flood to which the community will regulate new construction.

Many communities have elected to regulate to a flood standard higher than the minimum requirements of the NFIP. Those communities may do so in a number of ways. For example, a community may require new construction to be elevated a specific vertical distance above the base flood elevation (this is referred to as "freeboard"); a community may select a lower frequency flood as its regulatory flood; or a community may conduct hydrologic and hydraulic studies, on which flood hazard maps are based, in a manner different from the Flood Insurance Study prepared by the NFIP (e.g., the community may complete flood hazard studies based on development conditions at build-out, rather than following the NFIP procedure, which uses conditions in existence at the time the studies are completed; the community may include watersheds smaller than 1 mi^2 (2.6 km^2) in size in its analysis, rather than following the NFIP procedure, which neglects watersheds smaller than 1 mi^2 (2.6 km^2).

Use of the design flood concept will ensure that the requirements of this standard are not less restrictive than a community's requirements where that community has elected to exceed minimum NFIP requirements. In instances where a community has adopted the NFIP minimum requirements, the design flood described in this standard will default to the base flood.

Second, this standard also uses the terms "flood hazard area" and "flood hazard map" to correspond to and show the areas affected by the design flood. Again, in instances where a community has adopted the minimum requirements of the NFIP, the flood hazard area defaults to the NFIP's SFHA and the flood hazard map defaults to the FIRM.

Third, the concept of a Coastal A-Zone is used to facilitate application of load combinations contained in Chapter 2 of this standard. Coastal A-Zones lie landward of V-Zones, or landward of an open coast shoreline where V-Zones have not been mapped (e.g., the shorelines of the Great Lakes). Coastal A-Zones are subject to the effects of waves, high-velocity flows, and erosion, although not to the extent that V-Zones are. Like V-Zones, flood forces in Coastal A-Zones will be highly correlated with coastal winds or coastal seismic activity.

Coastal A-Zones are not delineated on flood hazard maps prepared by FEMA, but are zones where wave forces and erosion potential should be taken into consideration by designers. The following guidance is offered to designers to determine whether

@seismicisolation
@seismicisolation

or not an A-Zone in a coastal area can be considered a Coastal A-Zone.

For a Coastal A-Zone to be present, two conditions are required: (1) a still-water flood depth greater than or equal to 2.0 ft (0.61 m), and (2) breaking wave heights greater than or equal to 1.5 ft (0.46 m). Note that the still-water depth requirement is necessary, but is not sufficient by itself, to render an area a Coastal A-Zone. Many A-Zones will have still-water flood depths in excess of 2.0 ft (0.61 m) but will not experience breaking wave heights greater than or equal to 1.5 ft (0.46 m) and therefore should not be considered Coastal A-Zones. Wave heights at a given site can be determined using procedures outlined in USACE (2002) or similar references.

The 1.5 ft (0.46 m) breaking wave height criterion was developed from post-flood damage inspections, which show that wave damage and erosion often occur in mapped A-Zones in coastal areas, and from laboratory tests on breakaway walls that show that breaking waves 1.5 ft (0.46 m) in height are capable of causing structural failures in wood-frame walls (FEMA 2000).

C5.3 DESIGN REQUIREMENTS

Sections 5.3.4 (dealing with A-Zone design and construction) and 5.3.5 (dealing with V-Zone design and construction) of ASCE 7-98 were deleted in preparation of the 2002 edition of this standard. These sections summarized basic principles of flood-resistant design and construction [building elevation, anchorage, foundation, below design flood elevation (DFE) enclosures, breakaway walls, etc.]. Some of the information contained in these deleted sections was included in Section 5.3, beginning with ASCE 7-02. The design professional is also referred to ASCE/SEI Standard 24 (*Flood Resistant Design and Construction*) for specific guidance.

C5.3.1 Design Loads Wind loads and flood loads may act simultaneously at coastlines, particularly during hurricanes and coastal storms. This may also be true during severe storms at the shorelines of large lakes and during riverine flooding of long duration.

C5.3.2 Erosion and Scour The term *erosion* indicates a lowering of the ground surface in response to a flood event or in response to the gradual recession of a shoreline. The term *scour* indicates a localized lowering of the ground surface during a flood, due to the interaction of currents and/or waves with a structural element. Erosion and scour can affect the stability of foundations and can increase the local flood depth and flood loads acting on buildings and other structures. For these reasons, erosion and scour should be considered during load calculations and the design process. Design professionals often increase the depth of foundation embedment to mitigate the effects of erosion and scour and often site buildings away from receding shorelines (building setbacks).

C5.3.3 Loads on Breakaway Walls Floodplain management regulations require buildings in coastal high hazard areas to be elevated to or above the design flood elevation by a pile or column foundation. Space below the DFE must be free of obstructions to allow the free passage of waves and high-velocity waters beneath the building (FEMA 1993). Floodplain management regulations typically allow space below the DFE to be enclosed by insect screening, open lattice, or breakaway walls. Local exceptions are made in certain instances for shear walls, firewalls, elevator shafts, and stairwells. Check with the Authority Having Jurisdiction for specific requirements related to obstructions, enclosures, and breakaway walls.

Where breakaway walls are used, they must meet the prescriptive requirements of NFIP regulations or be certified by a registered professional engineer or architect as having been designed to meet the NFIP performance requirements. Meeting the NFIP performance requirements should be understood to mean that the structure to which breakaway walls are attached should withstand both of the following: (1) load combinations, including flood loads acting on the structure and the breakaway walls, up to the point of breakaway wall collapse, and (2) load combinations, including flood loads acting on the structure that remains following breakaway collapse, for flood conditions between those causing breakaway wall collapse and those associated with the design flood.

The prescriptive requirements call for breakaway wall designs that are intended to collapse at loads not less than 10 psf ($0.48\ \text{kN/m}^2$) and not more than 20 psf ($0.96\ \text{kN/m}^3$). Inasmuch as wind or earthquake loads often exceed 20 psf ($0.96\ \text{kN/m}^2$), breakaway walls may be designed for higher loads, provided the designer certifies that the walls have been designed to break away before base flood conditions are reached, without damaging the elevated building or its foundation. FEMA (1999a) provides guidance on how to meet the performance requirements for certification.

C5.4 LOADS DURING FLOODING

C5.4.1 Load Basis Water loads are the loads or pressures on surfaces of buildings and structures caused and induced by the presence of floodwaters. These loads are of two basic types: hydrostatic and hydrodynamic. Impact loads result from objects transported by floodwaters striking against buildings and structures or parts thereof. Wave loads can be considered a special type of hydrodynamic load.

C5.4.2 Hydrostatic Loads Hydrostatic loads are those caused by water either above or below the ground surface, free or confined, which is either stagnant or moves at velocities less than 5 ft/s (1.52 m/s). These loads are equal to the product of the water pressure multiplied by the surface area on which the pressure acts.

Hydrostatic pressure at any point is equal in all directions and always acts perpendicular to the surface on which it is applied. Hydrostatic loads can be subdivided into vertical downward loads, lateral loads, and vertical upward loads (uplift or buoyancy). Hydrostatic loads acting on inclined, rounded, or irregular surfaces may be resolved into vertical downward or upward loads and lateral loads based on the geometry of the surfaces and the distribution of hydrostatic pressure.

C5.4.3 Hydrodynamic Loads Hydrodynamic loads are those loads induced by the flow of water moving at moderate to high velocity above the ground level. They are usually lateral loads caused by the impact of the moving mass of water and the drag forces as the water flows around the obstruction. Hydrodynamic loads are computed by recognized engineering methods. In the coastal high hazard area, the loads from high-velocity currents due to storm surge and overtopping are of particular importance. USACE (2002) is one source of design information regarding hydrodynamic loadings.

Note that accurate estimates of flow velocities during flood conditions are very difficult to make, both in riverine and coastal flood events. Potential sources of information regarding velocities of floodwaters include local, state, and federal government agencies and consulting engineers specializing in coastal engineering, stream hydrology, or hydraulics.

@seismicisolation

As interim guidance for coastal areas, FEMA (2000) gives a likely range of flood velocities as

$$V = d_s/(1\text{ s}) \qquad \text{(C5.4-1)}$$

to

$$V = (gd_s)^{0.5} \qquad \text{(C5.4-2)}$$

where

V = Average velocity of water, ft/s (m/s);
d_s = Local still-water depth, ft (m); and
g = Acceleration due to gravity, 32.2 ft/s/s (9.81 m/s^2).

Selection of the correct value of a in Equation (5.4-1) will depend on the shape and roughness of the object exposed to flood flow, as well as the flow condition. As a general rule, the smoother and more streamlined the object, the lower the drag coefficient (shape factor). Drag coefficients for elements common in buildings and structures (round or square piles, columns, and rectangular shapes) will range from approximately 1.0 to 2.0, depending on flow conditions. However, given the uncertainty surrounding flow conditions at a particular site, ASCE 7-05 recommends a minimum value of 1.25 be used. Fluid mechanics texts should be consulted for more information on when to apply drag coefficients above 1.25.

C5.4.4 Wave Loads The magnitude of wave forces (lb/ft^2) (kN/m^2) acting against buildings or other structures can be 10 or more times higher than wind forces and other forces under design conditions. Thus, it should be readily apparent that elevating above the wave crest elevation is crucial to the survival of buildings and other structures. Even elevated structures, however, must be designed for large wave forces that can act over a relatively small surface area of the foundation and supporting structure.

Wave load calculation procedures in Section 5.4.4 are taken from USACE (2002) and Walton et al. (1989). The analytical procedures described by Equations (5.4-2) through (5.4-9) should be used to calculate wave heights and wave loads unless more advanced numerical or laboratory procedures permitted by this standard are used.

Wave load calculations using the analytical procedures described in this standard all depend on the initial computation of the wave height, which is determined using Equations (5.4-2) and (5.4-3). These equations result from the assumptions that the waves are depth limited and that waves propagating into shallow water break when the wave height equals 78% of the local still-water depth and that 70% of the wave height lies above the local still-water level. These assumptions are identical to those used by FEMA in its mapping of coastal flood hazard areas on FIRMs.

Designers should be aware that wave heights at a particular site can be less than depth-limited values in some cases (e.g., when the wind speed, wind duration, or fetch is insufficient to generate waves large enough to be limited in size by water depth, or when nearby objects dissipate wave energy and reduce wave heights). If conditions during the design flood yield wave heights at a site less than depth-limited heights, Equation (5.4-2) may overestimate the wave height and Equation (5.4-3) may underestimate the still-water depth. Also, Equations (5.4-4) through (5.4-7) may overstate wave pressures and forces when wave heights are less than depth-limited heights. More advanced numerical or laboratory procedures permitted by this section may be used in such cases, in lieu of Equations (5.4-2) through (5.4-7).

It should be pointed out that present NFIP mapping procedures distinguish between A-Zones and V-Zones by the wave heights expected in each zone. Generally speaking, A-Zones are designated where wave heights less than 3 ft (0.91 m) in height are expected. V-Zones are designated where wave heights equal to or greater than 3 ft (0.91 m) are expected. Designers should proceed cautiously, however. Large wave forces can be generated in some A-Zones, and wave force calculations should not be restricted to V-Zones. Present NFIP mapping procedures do not designate V-Zones in all areas where wave heights greater than 3 ft (0.91 m) can occur during base flood conditions. Rather than rely exclusively on flood hazard maps, designers should investigate historical flood damages near a site to determine whether or not wave forces can be significant.

C5.4.4.2 Breaking Wave Loads on Vertical Walls Equations used to calculate breaking wave loads on vertical walls contain a coefficient, C_p. Walton et al. (1989) provide recommended values of the coefficient as a function of probability of exceedance. The probabilities given by Walton et al. (1989) are not annual probabilities of exceedance, but probabilities associated with a distribution of breaking wave pressures measured during laboratory wave tank tests. Note that the distribution is independent of water depth. Thus, for any water depth, breaking wave pressures can be expected to follow the distribution described by the probabilities of exceedance in Table C5.4-2.

This standard assigns values for C_p according to building category, with the most important buildings having the largest values of C_p. Category II buildings are assigned a value of C_p corresponding to a 1% probability of exceedance, which is consistent with wave analysis procedures used by FEMA in mapping coastal flood hazard areas and in establishing minimum floor elevations. Category I buildings are assigned a value of C_p corresponding to a 50% probability of exceedance, but designers may wish to choose a higher value of C_p. Category III buildings are assigned a value of C_p corresponding to a 0.2% probability of exceedance, while Category IV buildings are assigned a value of C_p corresponding to a 0.1% probability of exceedance.

Breaking wave loads on vertical walls reach a maximum when the waves are normally incident (direction of wave approach is perpendicular to the face of the wall; wave crests are parallel to the face of the wall). As guidance for designers of coastal buildings or other structures on normally dry land (i.e., flooded only during coastal storm or flood events), it can be assumed that the direction of wave approach will be approximately perpendicular to the shoreline. Therefore, the direction of wave approach relative to a vertical wall will depend on the orientation of the wall relative to the shoreline. Section 5.4.4.4 provides a method for reducing breaking wave loads on vertical walls for waves not normally incident.

C5.4.5 Impact Loads Impact loads are those that result from logs, ice floes, and other objects striking buildings, structures, or parts thereof. USACE (1995) divides impact loads into three categories: (1) normal impact loads, which result from the isolated impacts of normally encountered objects; (2) special impact loads, which result from large objects, such as broken up ice floes and accumulations of debris, either striking or resting against a building, structure, or parts thereof; and (3) extreme impact loads, which result from very large objects, such as boats, barges, or collapsed buildings, striking the building, structure, or component under consideration. Design for extreme impact loads is not practical for most buildings and structures. However, in cases where there is a high probability that a Category III or IV structure (see Table 1.5-1) will be exposed to extreme impact loads during the design flood, and where the resulting damages will be very severe, consideration of extreme impact loads

@seismicisolation

may be justified. Unlike extreme impact loads, design for special and normal impact loads is practical for most buildings and structures.

The recommended method for calculating normal impact loads has been modified beginning with ASCE 7-02. Previous editions of ASCE 7 used a procedure contained in USACE (1995) [the procedure, which had been unchanged since at least 1972, relied on an impulse-momentum approach with a 1,000 lb (4.5 kN) object striking the structure at the velocity of the floodwater and coming to rest in 1.0 s]. Work (Kriebel et al. 2000, Haehnel and Daly 2001) has been conducted to evaluate this procedure through a literature review and laboratory tests. The literature review considered riverine and coastal debris, ice floes and impacts, ship berthing and impact forces, and various methods for calculating debris loads (e.g., impulse-momentum, work-energy). The laboratory tests included log sizes ranging from 380 lb (1.7 kN) to 730 lb (3.3 kN) traveling at up to 4 ft/s (1.2 m/s).

Kriebel et al. (2000) and Haehnel and Daly (2001) conclude that (1) an impulse-momentum approach is appropriate; (2) the 1,000 lb (4.5 kN) object is reasonable, although geographic and local conditions may affect the debris object size and weight; (3) the 1.0 s impact duration is not supported by the literature or by laboratory tests—a duration of impact of 0.03 s should be used instead; (4) a half-sine curve represents the applied load and resulting displacement well; and (5) setting the debris velocity equivalent to the flood velocity is reasonable for all but the largest objects in shallow water or obstructed conditions.

Given the short-duration impulsive loads generated by flood-borne debris, a dynamic analysis of the affected building or structure may be appropriate. In some cases (e.g., when the natural period of the building is much greater than 0.03 s), design professionals may wish to treat the impact load as a static load applied to the building or structure (this approach is similar to that used by some following the procedure contained in Section C5.3.3.5 of ASCE 7-98).

In either type of analysis—dynamic or static—Equation (C5.4-3) provides a rational approach for calculating the magnitude of the impact load:

$$F = \frac{\pi W V_b C_I C_O C_D C_B R_{\max}}{2g\Delta t} \qquad \text{(C5.4-3)}$$

where

F = Impact force, lb (N);
W = Debris weight, lb (N);
V_b = Velocity of object (assume equal to velocity of water, V), ft/s (m/s);
g = Acceleration due to gravity, 32.2 ft/s^2 (9.81 m/s^2);
Δt = Impact duration (time to reduce object velocity to zero), s;
C_I = Importance coefficient (see Table C5.4-1);
C_O = Orientation coefficient, 0.8;
C_D = Depth coefficient (see Table C5.4-2, Figure C5.4-1);
C_B = Blockage coefficient (see Table C5.4-3, Figure C5.4-2); and
$R_{\max}$ = Maximum response ratio for impulsive load (see Table C5.4-4).

The form of Equation (C5.4-3) and the parameters and coefficients are discussed in the following text:

Basic Equation. The equation is similar to the equation used in ASCE 7-98, except for the $\pi/2$ factor (which results from the half-sine form of the applied impulse load) and the coefficients C_I, C_O, C_D, C_B, and $R_{\max}$. With the coefficients set equal to 1.0, the equation reduces to $F = \pi W V_b / 2g\Delta t$ and calculates the maximum static load from a head-on impact of a debris object. The coefficients have been added to allow design professionals to "calibrate" the resulting force to local flood, debris, and building characteristics. The approach is similar to that used by ASCE 7 in calculating wind, seismic, and other loads. A scientifically based equation is used to match the physics, and the results are modified by coefficients to calculate realistic load magnitudes. However, unlike wind, seismic, and other loads, the body of work associated with flood-borne debris impact loads does not yet account for the probability of impact.

Table C5.4-1. Values of Importance Coefficient, C_I.

Risk Category	C_I
I	0.6
II	1.0
III	1.2
IV	1.3

Table C5.4-2. Values of Depth Coefficient, C_D.

Building Location in Flood Hazard Zone and Water Depth	C_D
Floodway or V-Zone	1.0
A-Zone, still-water depth > 5ft	1.0
A-Zone, still-water depth = 4ft	0.75
A-Zone, still-water depth = 3ft	0.5
A-Zone, still-water depth = 2ft	0.25
Any flood zone, still-water depth < 1ft	0.0

Debris Object Weight. A 1,000 lb (4.5 kN) object can be considered a reasonable average for flood-borne debris (no change from ASCE 7-98). This represents a reasonable weight for trees, logs, and other large woody debris that is the most common form of damaging debris nationwide. This weight corresponds to a log approximately 30 ft (9.1 m) long and just under 1 ft (0.3 m) in diameter. The 1,000 lb (4.5 kN) object also represents a reasonable weight for other types of debris ranging from small ice floes, to boulders, to manufactured objects.

However, design professionals may wish to consider regional or local conditions before the final debris weight is selected. The following text provides additional guidance. In riverine floodplains, large woody debris (trees and logs) predominates, with weights typically ranging from 1,000 lb (4.5 kN) to 2,000 lb (9.0 kN). In the Pacific Northwest, larger tree and log sizes suggest a typical 4,000 lb (18.0 kN) debris weight. Debris weights in riverine areas subject to floating ice typically range from 1,000 lb (4.5 kN) to 4,000 lb (18.0 kN). In arid or semiarid regions, typical woody debris may be less than 1,000 lb (4.5 kN). In alluvial fan areas, nonwoody debris (stones and boulders) may present a much greater debris hazard. Debris weights in coastal areas generally fall into three classes: in the Pacific Northwest, a 4,000 lb (18.0 kN) debris weight owing to large trees and logs can be considered typical; in other coastal areas where piers and large pilings are available locally, debris weights may range from 1,000 lb (4.5 kN) to 2,000 lb (9.0 kN); and in other coastal areas where large logs and pilings are not expected, debris will likely be derived from failed decks, steps, and building components and will likely average less than 500 lb (2.3 kN) in weight.

Debris Velocity. The velocity with which a piece of debris strikes a building or structure will depend on the nature of the debris and the velocity of the floodwaters. Small pieces of floating debris, which are unlikely to cause damage to buildings or other structures, will typically travel at the velocity of the floodwaters, in both riverine and coastal flood situations. However, large debris, such as trees, logs, pier pilings, and other large debris capable of causing damage, will likely travel at something less than the velocity of the floodwaters. This reduced velocity of large debris objects results in large part from debris dragging along the bottom and/or being slowed by prior collisions. Large riverine debris traveling along the floodway (the deepest part of the channel that conducts the majority of the flood flow) is most likely to travel at speeds approaching that of the floodwaters. Large riverine debris traveling in the floodplain (the shallower area outside the floodway) is more likely to be traveling at speeds less than that of the floodwaters for those reasons stated in the preceding text. Large coastal debris is also likely to be traveling at speeds less than that of the floodwaters. Equation (C5.4-3) should be used with the debris velocity equal to the flow velocity because the equation allows for reductions in debris velocities through application of a depth coefficient, C_D, and an upstream blockage coefficient, C_B.

Duration of Impact. A detailed review of the available literature (Kriebel et al. 2000), supplemented by laboratory testing, concluded the previously suggested 1.0 s duration of impact is much too long and is not realistic. Laboratory tests showed that measured impact durations (from initial impact to time of maximum force Δt) varied from 0.01 s to 0.05 s (Kriebel et al. 2000). Results for one test, for example, produced a maximum impact load of 8,300 lb (37,000 N) for a log weighing 730 lb (3,250 N), moving at 4 ft/s (1.2 m/s), and impacting with a duration of 0.016 s. Over all the test conditions, the impact duration averaged about 0.026 s. The recommended value for use in Equation (C5.4-3) is therefore 0.03 s.

Coefficients C_I, C_O, C_D, and C_B. The coefficients are based in part on the results of laboratory testing and in part on engineering judgment. The values of the coefficients should be considered interim, until more experience is gained with them.

The *importance coefficient,* C_I, is generally used to adjust design loads for the structure category and hazard to human life following ASCE 7-98 convention in Table 1.5-1. Recommended values given in Table C5.4-1 are based on a probability distribution of impact loads obtained from laboratory tests in Haehnel and Daly (2001).

The *orientation coefficient,* C_O, is used to reduce the load calculated by Equation (C5.4-3) for impacts that are oblique, not head on. During laboratory tests (Haehnel and Daly 2001) it was observed that although some debris impacts occurred as direct or head-on impacts that produced maximum impact loads, most impacts occurred as eccentric or oblique impacts with reduced values of the impact force. Based on these measurements, an orientation coefficient of $C_O = 0.8$ has been adopted to reflect the general load reduction observed due to oblique impacts.

The *depth coefficient,* C_D, is used to account for reduced debris velocity in shallow water due to debris dragging along the bottom. Recommended values of this coefficient are based on typical diameters of logs and trees, or on the anticipated diameter

@seismicisolation
@seismicisolation

of the root mass from drifting trees that are likely to be encountered in a flood hazard zone. Kriebel et al. (2000) suggest that trees with typical root mass diameters will drag the bottom in depths of less than 5 ft (1.5 m), while most logs of concern will drag the bottom in depths of less than 1 ft (0.30 m). The recommended values for the depth coefficient are given in Table C5.4-2 and Figure C5.4-1. No test data are available to fully validate the recommended values of this coefficient. When better data are available, designers should use them in lieu of the values contained in Table C5.4-2 and Figure C5.4-1.

The *blockage coefficient,* C_B, is used to account for the reductions in debris velocities expected due to screening and sheltering provided by trees or other structures within about 10 log lengths [300 ft (91.4 m)] upstream from the building or structure of interest. Kriebel et al. (2000) quote other studies in which dense trees have been shown to act as a screen to remove debris and shelter downstream structures. The effectiveness of the screening depends primarily on the spacing of the upstream obstructions relative to the design log length of interest. For a 1,000-lb (453.6 kg) log, having a length of about 30 ft (9.1 m), it is therefore assumed that any blockage narrower than 30 ft (9.1 m) would trap some or all of the transported debris. Likewise, typical root mass diameters are on the order of 3 to 5 ft (0.91 to 1.5 m), and it is therefore assumed that blockages of this width would fully trap any trees or long logs. Recommended values for the blockage coefficient are given in Table C5.4-3 and Figure C5.4-2 based on interpolation between these limits. No test data are available to fully validate the recommended values of this coefficient.

The *maximum response ratio,* R_{max}, is used to increase or decrease the computed load, depending on the degree of compliance of the building or building component being struck by debris. Impact loads are impulsive in nature, with the force rapidly increasing from zero to the maximum value in time Δt, then decreasing to zero as debris rebounds from the structure. The actual load experienced by the structure or component will depend on the ratio of the impact duration Δt relative to the natural period of the structure or component, T_n. Stiff or rigid buildings and structures with natural periods similar to the impact duration will see an amplification of the impact load. More flexible buildings and structures with natural periods greater than approximately four times the impact duration will see a reduction of the impact load. Likewise, stiff or rigid components will see an amplification of the impact load; more flexible components will see a reduction of the impact load. Successful use of Equatoin (C5.4-3), then, depends on estimation of the natural period of the building or component being struck by flood-borne debris. Calculating the natural period can be carried out using established methods that take building mass, stiffness, and configuration into account. One useful reference is Appendix C of ACI 349 (1985). Design professionals are also referred to Chapter 9 of ASCE 7-10 for additional information.

Natural periods of buildings generally vary from approximately 0.05 s to several seconds (for high-rise, moment frame structures). For flood-borne debris impact loads with a duration of 0.03 s, the critical period (above which loads are reduced) is approximately 0.11 s (see Table C5.4-4). Buildings and structures with natural periods above approximately 0.11 s will see a reduction in the debris impact load, whereas those with natural periods below approximately 0.11 s will see an increase.

Recent shake table tests of conventional, one- to two-story wood-frame buildings have shown natural periods ranging from approximately 0.14 s (7 Hz) to 0.33 s (3 Hz), averaging approximately 0.20 s (5 Hz). Elevating these types of structures for flood-resistant design purposes will act to increase these natural periods. For the purposes of flood-borne debris impact load calculations, a natural period of 0.5 to 1.0 s is recommended for one- to three-story buildings elevated on timber piles. For one- to three-story buildings elevated on masonry columns, a similar range of natural periods is recommended. For one- to three-story buildings elevated on concrete piles or columns, a natural period of 0.2 to 0.5 s is recommended. Finally, design professionals are referred to Section 12.8.2 of this standard, where an approximate natural period for 1- to 12-story buildings [story height equal to or greater than 10 ft (3 m)], with concrete and steel moment-resisting frames, can be approximated as 0.1 times the number of stories.

Special Impact Loads. USACE (1995) states that, absent a detailed analysis, special impact loads can be estimated as a uniform load of 100 lb/ft (1.48 kN/m), acting over a 1 ft (0.31 m) high horizontal strip at the design flood elevation or lower. However, Kriebel et al. (2000) suggest that this load may be too small for some large accumulations of debris and suggest an alternative approach involving application of the standard drag force expression

$$F = (1/2)C_D \rho A V^2 \qquad \text{(C5.4-4)}$$

where

F = Drag force due to debris accumulation, lb (N);
V = Flow velocity upstream of debris accumulation, ft/s (m/s);
A = Projected area of the debris accumulation into the flow, approximated by depth of accumulation times width of accumulation perpendicular to flow, ft^2 (m^2);
ρ = Density of water, slugs/ft^3 (kg/m^3); and
C_D = Drag coefficient = 1.

This expression produces loads similar to the 100 lb/ft (1.48 kN/m) guidance from USACE (1995) when the debris depth is assumed to be 1 ft (0.31 m) and when the velocity of the floodwater is 10 ft/s (3m/s). Other guidance from Kriebel et al. (2000) and Haehnel and Daly (2001) suggests that the depth of debris accumulation is often much greater than 1 ft (0.31 m) and is only limited by the water depth at the structure. Observations of debris accumulations at bridge piers listed in these references show typical depths of 5 to 10 ft (1.5 to 3 m), with horizontal widths spanning between adjacent bridge piers whenever the spacing of the piers is less than the typical log length. If debris accumulation is of concern, the design professional should specify the projected area of the debris accumulation based on local observations and experience and apply Equation (C5.4-4) to predict the debris load on buildings or other structures.

CHAPTER C6
TSUNAMI LOADS AND EFFECTS

C6.1 GENERAL REQUIREMENTS

C6.1.1 Scope The 2022 edition of the ASCE 7 Tsunami Loads and Effects chapter is applicable only to the states of Alaska, Washington, Oregon, California, and Hawaii, which are Tsunami Prone Region that have quantifiable probabilistic hazards resulting from tsunamigenic earthquakes with subduction faulting (Table C6.1-1). The Tsunami Design Zone (TDZ) is the area vulnerable to being flooded or inundated by the Maximum Considered Tsunami (MCT), which is taken as having a 2% probability of being exceeded in a 50-year period, or 1:2,475 annual probability of exceedance. The MCT constitutes the design event, consisting of the inundation depths and flow velocities taken at the stages of inflow and outflow most critical to the structure (Chock 2015, 2016).

Other causes of local tsunamis include large landslides near the coast or underwater and undersea volcanic eruptions. In Alaska, there is a history of coseismic landslides generated in fjords during major earthquakes.

For other states, there is insufficient analysis at present to reliably quantify the probabilistic hazard of landslide-induced local tsunami. As of 2020, PTHA is lacking for some other regions with historic tsunamis (such as Guam, Commonwealth of the Northern Marianas, American Samoa, Puerto Rico, and US Virgin Islands), so these regions are not covered. However, for Tsunami Risk Categories III and IV buildings and other structures, it is recommended that there be consideration of performing probabilistic site-specific tsunami hazard analysis to use as a basis for implementing tsunami-resistant design with these provisions.

Table C6.1-1 provides a general assessment of the exposure of the five western states to tsunami hazard.

Because of the high hydrodynamic forces exerted by tsunamis, one- and two-family dwellings and low-rise buildings of light-frame construction do not survive significant tsunami loading, as indicated by numerous post-tsunami forensic engineering surveys of the major tsunami events of the past decade. Therefore, it is not practical to include tsunami design requirements for these types of low-rise structures. Impractical applications to low-rise light-frame construction should be avoided. As is typical in flood-prone regions, midrise light-frame construction can be built on a pedestal structure to provide sufficient elevation to enable a tsunami-resistant design.

The state or local government should determine a threshold height for where tsunami-resilient design requirements for Risk Category II buildings shall apply in accordance with the state or local statute adopting the building code with tsunami-resilient requirements. The height threshold should be chosen to be appropriate for both reasonable Life Safety and reasonable economic cost to resist tsunami loads. The threshold height would depend on their community's tsunami hazard, tsunami response procedures, and whole community disaster resilience goals. Considerations of evacuation egress time from a local community would also be a consideration. When evacuation travel times exceed the available time to tsunami arrival, there is a greater need for vertical evacuation into an ample number of nearby buildings. The inventory and design vintage of existing taller buildings that may offer some increased safety can also be a consideration for determining the shortfall of such possible refuges. In summary, multiagency stakeholders in coordination with emergency management and design and construction professionals should evaluate the tsunami risks to each local community's public safety and Critical Facilities for response and recovery from the MCT and should use that information to rationally determine the threshold height of application of the tsunami provisions to Risk Category II buildings.

The technique demonstrated by Carden et al. (2015) can be used to evaluate the systemic level of tsunami resistance provided by the ASCE 7 seismic design requirements. Past this point of structural system parity between tsunami and seismic demand, additional investment into the lateral-force-resisting system would become necessary for tsunami resistance. For any structure, it may be necessary to provide enhanced local resistance of structural components subjected to tsunami inundation, in accordance with the provisions of Chapter 6, particularly if the tsunami is close to a shipping port.

From the previous discussion, note that structural engineering and regional tsunami science expertise is necessary to evaluate several important technical factors relevant to the jurisdiction's decision to establish a threshold height of applicability for Risk Category II buildings and structures (Chock et al. 2018). The referenced paper provides initial guidance for the process of examining the entire Tsunami Design Zone for a local code jurisdiction.

Tsunami Risk Category II structures taller than the designated height threshold, all Tsunami Risk Category III, and all Tsunami Risk Category IV buildings and other structures are subject to these requirements. Risk Category II buildings shorter than the designated height threshold are not required to be designed for tsunami loads. Accordingly, it is important for the community to have Tsunami Evacuation Maps and operational response procedures, recognizing the inventory of Risk Category II buildings not designated to be designed for tsunami effects, which would therefore be vulnerable to tsunami damage.

Mitigation of tsunami risk requires a combination of emergency preparedness for evacuation in addition to providing structural resilience of Critical Facilities, infrastructure, and key resources necessary for immediate response and economic and social recovery. Risk Category I and low-rise Risk Category II buildings are not required to be designed against any tsunami

@seismicisolation

Table C6.1-1. Exposure of the Five Western States to Tsunami Hazard.

State	Population at Direct Risk[a]	Profile of Economic Assets and Critical Infrastructure
California	275,000 residents plus another 400,000 to 2 million tourists; 840 miles of coastline Total resident population of area at immediate risk of post-tsunami impacts: 1,950,000[b]	Over $200 billion plus three major airports (SFO, OAK, SAN) and one military port, five very large ports, one large port, five medium ports
Oregon	25,000 residents plus another 55,000 tourists; 300 miles of coastline Total resident population of area at immediate risk of post-tsunami impacts: 100,000[b]	$8.5 billion plus essential facilities, two medium ports, one fuel depot hub
Washington	45,000 residents plus another 20,000 tourists; 160 miles of coastline Total resident population of area at immediate risk of post-tsunami impacts: 900,000[b]	$4.5 billion plus essential facilities, one military port, two very large ports, one large port, three medium ports
Hawaii	About 200,000 residents plus another 175,000 or more tourists and approximately 1,000 buildings directly relating to the tourism industry[c]; 750 miles of coastline Total resident population of area at immediate risk of post-tsunami impacts: 400,000[c]	$40 billion, plus three international airports, one military port, one medium port, four other container ports, one fuel refinery intake port, three regional power plants, 100 government buildings
Alaska	105,000 residents, plus highly seasonal visitor count; 6,600 miles of coastline Total resident population of area at immediate risk of post-tsunami impacts: 125,000[b]	Over $10 billion plus international airport's fuel depot, three medium ports, plus nine other container ports; 55 ports in total

event because they are at a higher risk of being fully inundated and collapsing during a major tsunami. Communities in the Tsunami-Prone Region should be enabled with tsunami warning systems and emergency operations plans for evacuation because Risk Category I and low-rise Risk Category II buildings should not be occupied during a tsunami. A tsunami warning and evacuation procedure consists of a plan and procedure developed and adopted by a community that has a system to act on a tsunami warning from the designated National Oceanic and Atmospheric Administration (NOAA) tsunami warning center at all hours using two independent means—a 24 h operational site to receive the warning and established methods of transmitting the warning that will be received by the affected population—and has established and designated evacuation routes for its citizens to either high ground or to a designated Tsunami Vertical Evacuation Refuge Structure. At present, the states of Alaska, Washington, Oregon, California, and Hawaii already have tsunami warning and evacuation procedures. A NOAA TsunamiReady community would include this procedure. In these states, it is recognized by federal, state, and local governments that mitigation of tsunami risk to public safety requires emergency preparedness for evacuation.

The ASCE Board authorized the SEI and COPRI funding necessary for Tsunami Design Zone mapping and Offshore Tsunami Amplitude, within the project for this standard. In 2013, the NOAA National Tsunami Hazard Mitigation Program (NTHMP) Modeling and Mapping Subcommittee convened a Probabilistic Tsunami Hazard Analysis (PTHA) working group and conducted a comparison of prototype probabilistic tsunami inundation maps produced in 2013 by two independent researchers, including a team from the University of Washington as well as the Pacific Marine Environmental Laboratory (PMEL) team performing the work for ASCE, to validate the key procedures of the PTHA methodology. The study was reviewed and advised by a broad panel of experts of the Modeling and Mapping Subcommittee of NTHMP. The USGS team involved in the scientific consensus process for seismic source characterization for the National Earthquake Hazards Reduction Program and ASCE seismic maps were also included in this panel. State geologists and tsunami modelers from all five western states also participated. The results of this 2013–2014 peer review phase (California Geological Survey 2015) were incorporated into the production process of the 2014–2015 ASCE 7 mapping project. The PTHA methodology used to develop the Tsunami Design Zone Maps is explained in Section C6.7.

The ASCE Tsunami Design Geodatabase (version 2022-1.0) includes updated Tsunami Design Zone data based on high-resolution Digital Elevation Models (DEMs), updated probabilistic tsunami hazard analysis (PTHA), and improved inundation modeling for the state of California, the Salish Sea region of the state of Washington, the City and County of Honolulu, and the County of Hawaii. The methodology for the updates complies with the requirements of Section 6.7 of ASCE 7-22. These updates included the improved Tsunami Design Zone, Runup Elevations, and Inundation Depth Points. In certain areas of California and Hawaii, zones with 3 ft (0.914 m) or less inundation depth were also identified. For Risk Categories II and III, per Section 6.1.1, tsunami structural design becomes required where the inundation depth is greater than 3 ft (0.914 m) at any location within the intended footprint of the structure. The boundaries of the California, Washington, and the County of Hawaii high-resolution Tsunami Design Zone areas were transitioned to the Runup Elevations in the surrounding lower-resolution areas of the ASCE Tsunami Design Geodatabase to provide a smooth transition between the data sets. The

@seismicisolation

areas modeled in high-resolution are shown in Figure C6.1-2(a), (b), and (c). A description of the analysis and geoprocessing is provided in Thio (2019) and Wilson et al. (2020) for California, in Thio (2020) for Washington, in Robertson (2019) for Honolulu, and in Wei (2016) for the County of Hawaii.

The final step of the PTHA process involves the inundation analysis to determine the runup. Runup geodata define the ground elevation where the tsunami inundation reaches its horizontal limit. The runup data set of the ASCE Tsunami Design Geodatabase includes these geocoded points defining the locations and elevations of the runup. The inundation limit on land is the smoothed extent line formed by these discrete runup points, and the Tsunami Design Zone essentially consists of the land area between the inundation limit line and the coastline. Review of the ASCE 7-16 Tsunami Design Zone Maps by the Tsunami Loads and Effects Subcommittee also included comparison with the results of two independent modelers conducting region-specific work. *ASCE 7-22 Tsunami Design Zone Maps for Selected Locations* provides 62 Tsunami Design Zone Maps rendered in PDF format and downloadable from https://doi.org/10.1061/9780784480748. The locations of these 62 maps are indicated by circles in Figure C6.1-1(a) to (i). For the purpose of defining the Tsunami Design Zone, these PDF maps are considered equivalent to the results served from the ASCE 7 Tsunami Design Geodatabase for the corresponding areas and are produced with the runup, GIS point data, and Tsunami Design Zone data in the Geodatabase.

ASCE 7-16 Tsunami Design Zone Maps for Selected Locations (ASCE 2017a) also includes a report prepared for ASCE, "Probabilistic Tsunami Design Maps for the ASCE 7-16 Standard," that describes the development of the 2,500-year probabilistic tsunami design zone maps and is suitable as an accompanying user manual.

The key data sets of the ASCE Tsunami Design Geodatabase are the runup points. These are organized by segments of coastline for each of the five western states [the extent is shown in Figure C6.1-1(a) to (i)].

The ASCE Tsunami Design Geodatabase data is web-based (http://asce7tsunami.online) and does not require proprietary software.

The effect of seismic subsidence, typically following the recognized deformation model of Okada (1985) illustrated in Figure C6.1-3, is accounted for within the modeling used to develop the mapped inundation limits of Figure 6.1-1. Figure C6.1-3 illustrates the effects of relative sea level rise and seismic subsidence on tsunami inundation. Note that in subduction regions, the long-term trend of ground elevation may be uplift, but the engineer is not to consider extrapolating this trend to reduce the design inundation since the subduction earthquake mechanism will result in this temporal uplift being eliminated by seismic subsidence.

A general outline of the main steps in the tsunami analysis and design requirements is given in Figure C6.1-4.

C6.2 DEFINITIONS

The ASCE definitions were developed after a review of international literature before 2013 that in general did not have uniform consistency of tsunami terminology. In addition, some references may utilize waveform terminology relevant to documenting the local effects of historic tsunamis but were not directly applicable to the specification of a probabilistic tsunami for design purposes. However, the publication of a revised tsunami glossary by the Intergovernmental Oceanographic Commission (2013) should lead to greater consistency, and the ASCE terminology is compatible with that document.

In particular, as illustrated in Figure 6.2-1, key terms for tsunami definition are the Maximum Considered Tsunami, the Offshore Tsunami Amplitude, inundation depth, runup elevation, and the inundation limit.

This standard defines the size of a probabilistic Maximum Considered Tsunami at a standardized offshore depth of 328 ft (100 m), using its amplitude above or below the ambient sea level. This level is different from the peak to trough tsunami height. In site-specific tsunami hazard analysis, a Reference Sea Level of Mean High Water is primarily used in inundation modeling to account for tidal fluctuations during tsunamis.

The tsunami inundations in ASCE 7 have been computed using digital elevation models (DEMs) developed by NOAA's National Center for Environmental Information for selected US coastal regions. Bathymetric, topographic, and shoreline data used in DEM compilation are obtained from various sources, including the National Centers for Environmental Information, US National Ocean Service, US Geological Survey, US Army Corps of Engineers, Federal Emergency Management Agency (FEMA), and other federal, state, and local government agencies, academic institutions, and private companies. The DEMs are referenced to the vertical tidal datum of Mean High Water (MHW) and the horizontal datum of World Geodetic System 1984 (WGS84). MHW is the average of all the high-water heights observed over the National Tidal Datum Epoch. The present National Tidal Datum Epoch is 1983 through 2001 and is actively considered for revision every 20 to 25 years. Accordingly on land, MHW is adopted as the common reference datum for ground elevation and tsunami runup elevations resulting from the inundation analysis for the Maximum Considered Tsunami. By this datum, the "shoreline" is set at the MHW, which is thereby elevation zero. Other adopted reference data may be used in practice, including, but not limited to, the North American Vertical Datum 88, also known as NAVD 88 (Zilkoski et al. 1992), and in such cases the results of a site-specific tsunami hazard analysis should be coordinated with and converted to the appropriate local reference datum. In addition to MHW, the ASCE Tsunami Design Geodatabase also includes data referenced to NAVD88 where available. Another key definition is the Froude number, the nondimensionalized flow velocity; in this chapter, when the Froude number is specified, the engineer should recognize that this number is explicitly defining a prescribed relationship of velocity as a function of inundation depth.

As of the 2022 edition of this standard, the Tsunami-Prone Region comprises the states of Alaska, Washington, Oregon, California, and Hawaii; this region is subject to the addition of other areas once further Probabilistic Tsunami Hazard Analyses are performed that demonstrate runup of greater than 3 ft (0.914 m).

C6.3 SYMBOLS AND NOTATION

Particular tsunami design symbology for which the user may desire clarification includes the following: V_w = General volume of displaced water that the engineer needs to calculate based on the loading condition and structural configuration. The loading equations use the symbol γ for weight density and ρ for mass density. Generally, this notation clarifies and distinguishes the fluid mechanics of hydrostatic effects from hydrodynamic effects.

C6.4 TSUNAMI RISK CATEGORIES

This standard classifies facilities in accordance with Risk Categories that recognize the importance or criticality of the facility. In the tsunami chapter, further modified definitions of the Risk Categories for Tsunami Risk Categories III and IV are included with respect to specific occupancy/functional criteria. Critical Facilities designated by local governments are included in Tsunami Risk Category III. Essential Facilities are included in Tsunami Risk Category IV.

@seismicisolation

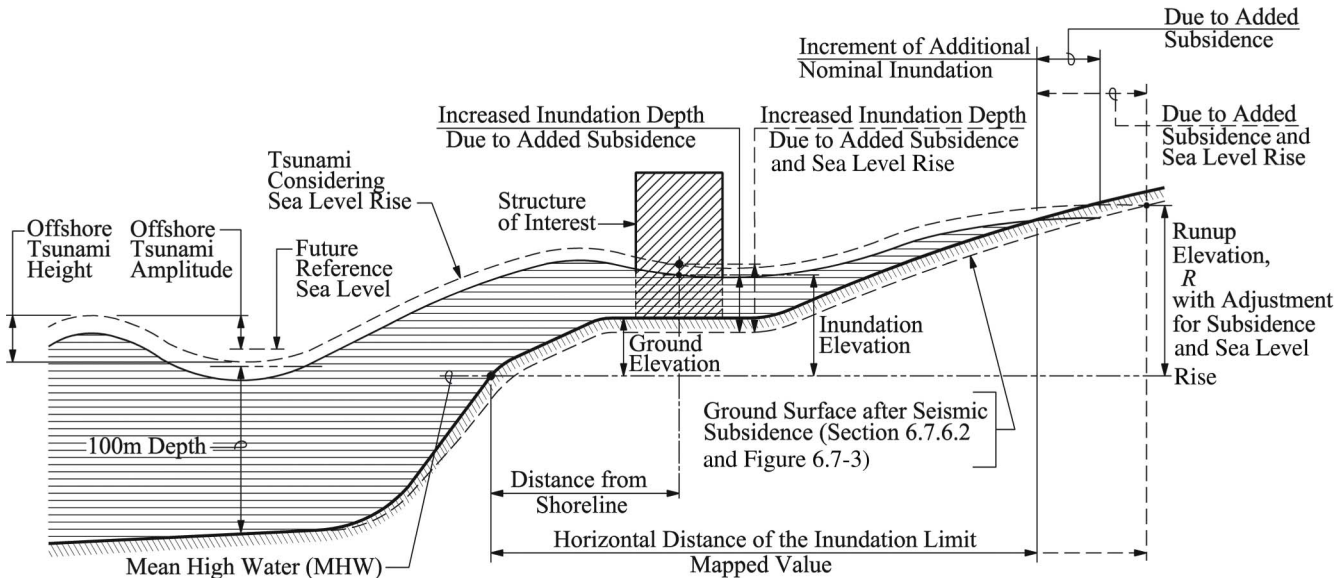

Figure C6.1-3. Effects of relative sea level change and regional seismic subsidence on tsunami inundation.

Critical Facilities are included in Tsunami Risk Category III only if they are so designated by local governments, such as power-generating stations, water-treatment facilities for potable water, wastewater-treatment facilities, and other public utility facilities not included in Risk Category IV. Critical Facilities are those needed for post-tsunami mission-critical functions or facilities that have more critical roles in community recovery and community services. Essential Facilities are those facilities necessary for emergency response. As approved by the ASCE Board of Direction in 2013, ASCE Policy Statement 518 (2013) states, "Critical infrastructure includes systems, facilities, and assets so vital that their destruction or incapacitation would have a debilitating impact on national security, the economy or public health, safety, and welfare." FEMA P-543 (2007) states, "Critical facilities comprise all public and private facilities deemed by a community to be essential for the delivery of vital services, protection of special populations, and the provision of other services of importance for that community." In general usage, the term Critical Facilities is used to describe all structures or other improvements that, because of their function, size, service area, or uniqueness, have the potential to cause serious bodily harm, extensive property damage, or disruption of vital socioeconomic activities if they are destroyed or damaged, or if their functionality is impaired.

Critical Facilities commonly include all public and private facilities that a community considers essential for the delivery of vital services and for the protection of the community. They usually include emergency response facilities (fire stations, police stations, rescue squads, and emergency operation centers, or EOCs), custodial facilities (jails and other detention centers, long-term care facilities, hospitals, and other health-care facilities), schools, emergency shelters, utilities (water supply, wastewater-treatment facilities, and power), communications facilities, and any other assets determined by the community to be of critical importance for the protection of the health and safety of the population.

The number and nature of Critical Facilities in a community can differ greatly from one jurisdiction to another, and these facilities usually include both public and private facilities. In this sense, each community needs to determine the relative importance of the publicly and privately owned facilities that deliver vital services, provide important functions, and protect special populations.

A number of Essential Facilities do not need to be included in Tsunami Risk Category IV because they should be evacuated before the tsunami arrival. This includes fire stations, ambulance facilities, and emergency vehicle garages. These facilities may be necessarily located within the Tsunami Design Zone because they must serve the public interest on a timely basis, but designing the structures for tsunami loads and effects could be prohibitively expensive, with minimal benefit to the resilience of the community. The evacuated emergency response resources would still be available after the tsunami. Also not included in Tsunami Risk Category IV are earthquake and hurricane shelters, because these types of shelters for other hazards are not to be used during a tsunami. Earthquake shelters in particular are postdisaster mass care facilities, since earthquakes have no effective pre-event warning. As such, these earthquake shelters do not serve any purpose for tsunami evacuation refuge before the arrival of a tsunami. Emergency aircraft hangars are also not included in Tsunami Risk Category IV, because these aircraft would need to be deployed outside of the inundation zone to ensure that they are functional after the tsunami. In coordination with the jurisdiction's emergency response and recovery plan, certain facilities could be considered for designation as Tsunami Risk Category II or III, if they are deemed not uniquely required for postdisaster operations or where such functionality can be sufficiently provided from a post-tsunami alternative facility.

Tsunami Vertical Evacuation Refuge Structures are included in Tsunami Risk Category IV because of their function as a safe refuge for evacuees during the tsunami. If health-care facilities with 50 or more resident patients are for some reason located in the Tsunami Design Zone, it is recommended that such facilities should also be designed in accordance with Tsunami Risk Category IV rather than Risk Category III. The height of the structure must afford a sufficient number of elevated floor levels for patient vertical evacuation, similar to a Tsunami Vertical Evacuation Refuge Structure, because of the difficulty with evacuating assisted-living patients in a timely manner before inundation.

@seismicisolation

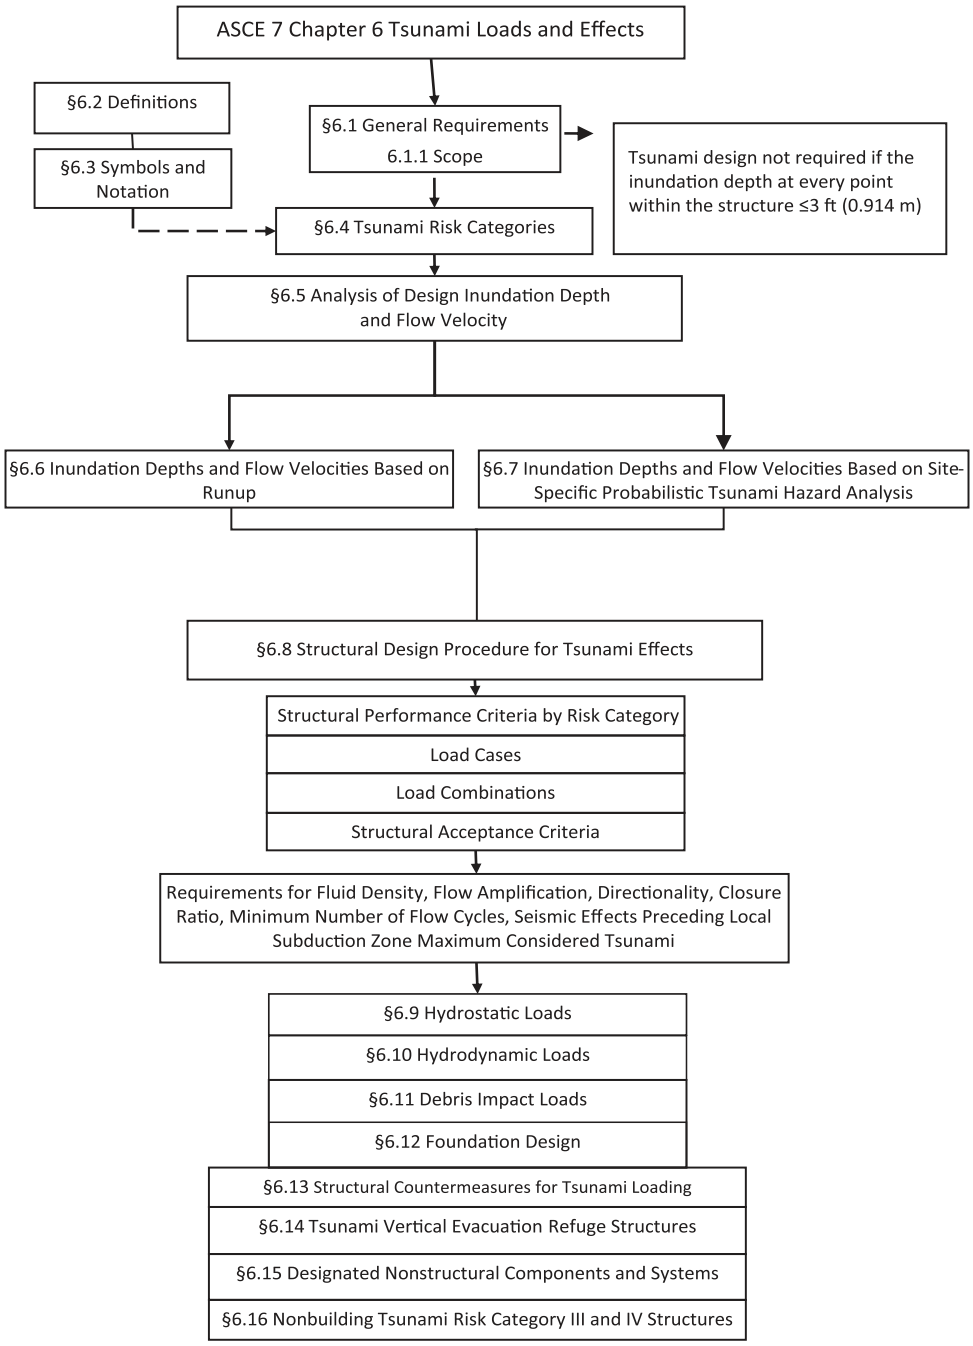

Figure C6.1-4. General organization of Chapter 6.

C6.5 ANALYSIS OF DESIGN INUNDATION DEPTH AND FLOW VELOCITY

There are two procedures for determining the inundation depth and velocities at a site: (1) Energy Grade Line Analysis, which takes the runup elevation and inundation limit indicated on the Tsunami Design Zone Map as the target solution point of a hydraulic analysis along the topographic transect from the shoreline to the point of runup; and (2) a site-specific inundation analysis of at least depth-averaged two-dimensional (2D) numerical modeling that uses the Offshore Tsunami Amplitude, the wave period that is a conserved property (during shoaling, the timescale of the overall tsunami wave hardly changes), and other waveform parameters as the input to a numerical simulation that includes a high-resolution Digital Elevation Model.

Energy Grade Line Analysis, which has been developed to produce conservative design flow parameters, is always performed for Tsunami Risk Category II, III, and IV structures. The site-specific inundation analysis procedure may or may not be required, depending on the structure's Tsunami Risk Category. Site-specific inundation analysis is not required, but may be used, for Tsunami Risk Category II and III structures. The site-specific inundation analysis procedure is performed for Tsunami Risk Category IV structures unless the Energy Grade Line Analysis shows the inundation depth to be less than 12 ft (3.66 m) at the structure. However, Tsunami Vertical Refuge

@seismicisolation

Structures shall always use site-specific inundation analysis, regardless of the inundation depth produced by the Energy Grade Line Analysis.

A precise computer simulation can capture two-dimensional flow and directionality effects that a linear transect analysis cannot, and so it is particularly useful as an additional due diligence investigation of flow characteristics for Risk Category IV structures. However, supposedly exact numerical codes do not include any allowance whatsoever for the uncertainty of the modeling technique, which may lead to underestimation of flow speed. The fundamental responsibility of engineering philosophy requires consideration of the consequences of underestimation to the risk of design failure, as opposed to the academic scientific philosophy that seeks the best mean value rendered with high precision without the burden of other concerns. The less precise Energy Grade Line Analysis developed by the ASCE Tsunami Loads and Effects Subcommitteee purposely includes that allowance for uncertainty, as well as providing a solution in the familiar context of well-established engineering hydraulic fundamentals that can aid an engineer's judgment. Therefore, the Energy Grade Line Analysis provides a measure of engineering statistical reliability that is used for establishing a proportion of the Energy Grade Line Analysis as a "floor value" below which various numerical model simulation techniques should not fall, particularly for flow velocity. To establish the appropriate statistical allowance and conservative bias in the Energy Grade Line Analysis method, 36,000 trial numerical code simulations were performed versus the Energy Grade Line Analysis method. Without this limitation, as is stated in Section 6.7.6.8, there would have been inconsistent reliabilities between the two methods. That is why for Risk Category IV structures of inherently high value, both techniques are valuable to perform, but for quite distinctly different but important reasons (two-dimensional flow characteristics and flow speed).

Table C6.5-1 indicates the necessary inundation depth and flow velocity analysis procedures in accordance with Section 6.5 for each tsunami risk category, for locations shown in the Tsunami Design Zone Map of Figure 6.1-1.

Table C6.5-2 indicates the necessary inundation depth and flow velocity analysis procedures in accordance with Section 6.5 per tsunami risk category for locations where the inundation limit is not shown in the Tsunami Design Zone Map of Figure 6.1-1 but where the Offshore Tsunami Amplitude is shown in Figure 6.7-1.

In certain regions and topographies, for example in remote areas of Alaska, detailed inundation limit mapping is not available. Where no inundation limit map is available from the Authority Having Jurisdiction, a runup based on the factor given in Equation (6.5-2), multiplied by the Offshore Tsunami Amplitude, can be used with the Energy Grade Line Analysis for Tsunami Risk Category II and III structures. The guidance of estimating runup elevation by this approximate factor multiplied by the Offshore Tsunami Amplitude is derived from Japanese research reported in Murata et al. (2010), together with runup relations developed by Synolakis (1986), Li (2000), and Li and Raichlen (2001, 2003); numerical simulations; and field observations from the 2011 Tohoku-Oki tsunami.

Since a large volume of literature exists on the prediction of tsunami runup by analytical methods, by laboratory experiments, and by numerical modeling, a method based on peer-reviewed literature may be used to refine the prediction of runup in certain cases. In these cases, the shoreline topography, Nearshore Profile Slope Angle, and offshore bathymetry should correspond to design conditions. Li and Raichlen (2001, 2003) present analytical expressions for calculating runup of solitary waves under breaking and nonbreaking conditions; Madsen and Schäffer (2010) summarize analytical expressions for runup of nonsolitary wave shapes such as *N*-waves and transient wave trains; and Didenkulova and Pelinovsky (2011) address runup amplification of solitary waves in U-shaped bays.

Figure C6.5-1 is primarily based on runup relations developed by Li and Raichlen for nonbreaking and breaking waves to predict the ratio of runup, R, to Offshore Tsunami Amplitude, H_T, as a function of Φ, the Nearshore Profile Slope Angle. The experiments were conducted for Nearshore Profile Slope Angles less than 1:50 and show a peak runup ratio near 4 and decreasing runup for shallow slopes. The envelope curve represents nearly an upper bound of predicted runup for the range of wave heights [16.4 ft to 65.6 ft (5 m to 20 m)], $0.05 \le H_T/h_o \le 0.2$, in areas where no inundation limit has been mapped. Figure C6.5-1 shows the runup relations used to determine the envelope curve. The maximum value of $R/H_T = 4.0$ follows the guidance from Murata et al. (2010). The minimum value of $R/H_T = 3.0$ is based on field observations from the 2011 Tohoku-Oki tsunami, as well as output from numerical models.

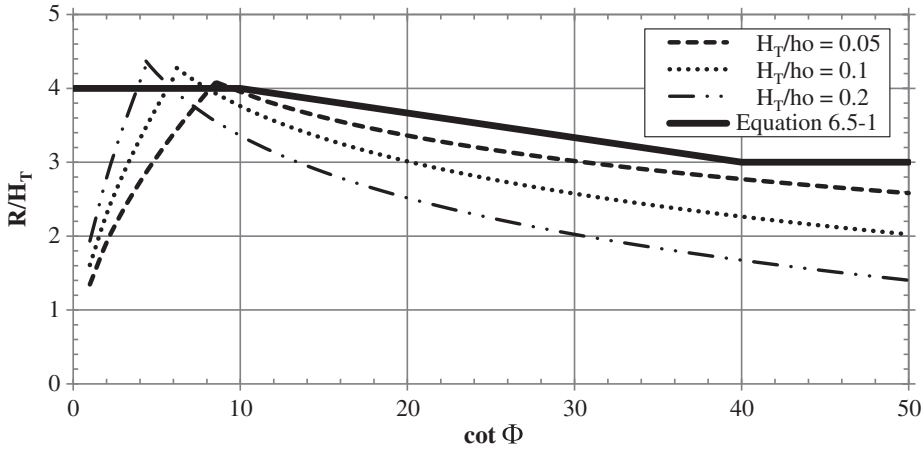

Figure C6.5-1. Runup ratio, R/H_T, as a function of the mean slope of the Nearshore Profile, cot Φ, for relative wave heights $H_T/h_o = 0.05$, 0.1, and 0.2.

Figure C6.5-2 presents the envelope equation of Figure C6.5-1 together with field observations from the 2011 Tohoku tsunami and the results of numerical and physical models of real and idealized runups, together with a large catalog of simulated runups for 36,000 possible combinations of Nearshore Profile Slope Angle and onshore topography. The field and numerical model data suggest that the relation between runup and Offshore Tsunami Amplitude is not greatly reduced as Nearshore Profile Slope Angle increases. In addition, the shallow slopes (high values of cotΦ) observed in the field fall outside of the range possible in physical experiments.

In coastal engineering practice, wave runup is commonly analyzed using a dimensionless parameter called surf similarity, or Iribarren number. The surf similarity parameter characterizes runup using a combination of wave steepness and slope that governs the way the wave evolves as it passes from offshore to onshore. Surf similarity parameter has been applied to tsunamis by Madsen and Schäffer (2010), Hughes (2004), and others. Use of the surf similarity parameter for runup is consistent with coastal engineering design worldwide.

Surf similarity parameter, ξ_{100}, for this application to tsunami engineering is defined as follows:

$$\xi_{100} = \frac{T_{TSU}}{\cot(\Phi)}\sqrt{g/2\pi H_T} \qquad \text{(C6.5-1)}$$

where Φ is the mean slope angle of the Nearshore Profile taken from the 328 ft (100 m) water depth to the Mean High Water Level elevation along the axis of the topographic transect for the site. H_T is the offshore tsunami amplitude, and T_{TSU} is the wave period of the tsunami at 328 ft (100 m) water depth. Runup ratios from field observations, as well as from physical and numerical modeling, are shown as a function of ξ_{100} in Figure C6.5-3 together with an envelope curve that encompasses most of the data. Outliers are in areas where wave focusing is expected to occur and for Monte Carlo simulations with very small crest heights relative to troughs, which alters relative runup values.

Using the surf similarity parameter allows a reduction in the relative runup height for cases where the surf similarity parameter is less than 6 or greater than 20. For the field values presented in Figure C6.5-3, 30% of the surf similarity values fall into the range that would allow for a reduction in relative runup height below the value of 4.

@seismicisolation

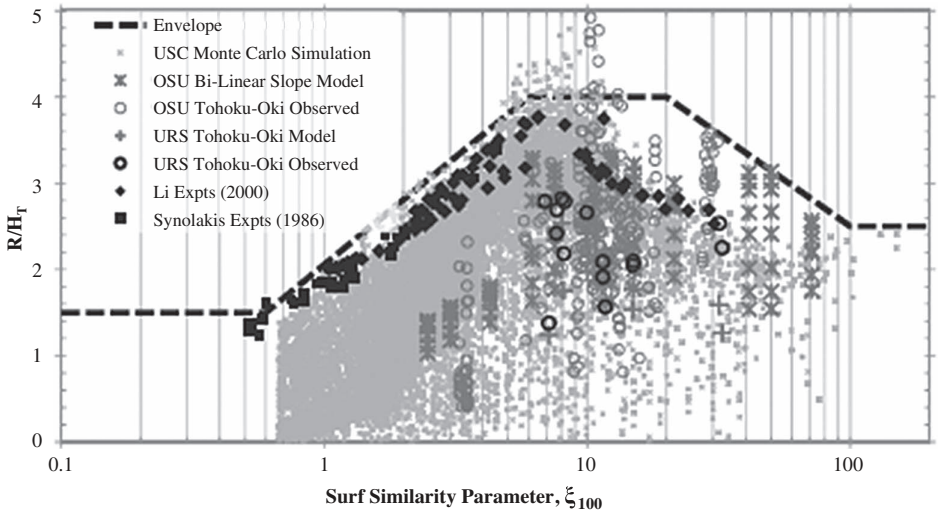

Figure C6.5-3. Runup ratio, R/H_T, as a function of the surf similarity parameter, ξ_{100}.

C6.5.3 Sea Level Change Sea level rise has not been incorporated into the Tsunami Design Zone Maps, and any additive effect on the inundation at the site should be explicitly evaluated. The approach taken for consideration of the effects of sea level rise is consistent with that given by the U.S. Army Corps of Engineers (2013). For a given Maximum Considered Tsunami, the runup elevation and inundation depth at the site are increased by at least the future projected relative sea level rise during the design life of the structure. The minimum design lifecycle of 50 years can be exceeded by the physical life span of many structures. Relative sea level change for a particular site may result from ground subsidence and long-term erosion, and change in local temperature of the ocean causing thermal expansion, as well as possible global effects by melting of ice sheets. Note that as the ASCE provisions for tsunami may later incorporate other areas with more significant relative sea level rise because of greater geologic (nonseismic) subsidence, this section on sea level rise would be more important. An example of this would be American Samoa and the other Pacific insular states and territories in the western Pacific Ocean associated with the United States, particularly where the habitable terrain elevation is low.

Historical sea level change trends over the past 150 years can be obtained from the NOAA Center for Operational Oceanographic Products and Services, which has been measuring sea level at tide stations along the US coasts. Changes in local relative mean sea level (MSL) have been computed at 128 long-term water level stations using a minimum span of 30 years of observations at each location (http://tidesandcurrents.noaa.gov/sltrends/: "Tide gauge measurements are made with respect to a local fixed reference level on land; therefore, if there is some long-term vertical land motion occurring at that location, the relative MSL trend measured there is a combination of the global sea level rate and the local vertical land motion.")

C6.6 INUNDATION DEPTHS AND FLOW VELOCITIES BASED ON RUNUP

C6.6.1 Maximum Inundation Depth and Flow Velocities Based on Runup Calculated flow velocities are subject to minimum and maximum limits based on observational data from past tsunamis of significant inundation depth. The upper limit of 50 ft/s (15.2 m/s) in Section 6.6 already includes a 1.5 factor on the velocity that is greater than any on-land flow velocity that the committee has examined from field or video evidence. The flow velocity upper limit is therefore applicable subsequent to any flow amplification factors caused by obstructions in the built environment, per Sections 6.6.5, 6.7.6.6, or 6.8.5.

In a Monte Carlo simulation of hundreds of variations of terrain profiles where the Energy Grade Line Analysis was compared to numerical models, it was found that cases of negative terrain slope gradient would cause the Energy Grade Line Analysis to fail to converge on a solution. To deal with the possibility of such cases in which local downslope acceleration of flow would occur, but to retain the simplicity of the analysis, a conservative adjustment of the runup elevation is prescribed in method 2 of Section 6.6.1, which essentially increases the energy grade line. Alternatively, a site-specific inundation analysis may be performed per method 1 of Section 6.6.1.

C6.6.2 Energy Grade Line Analysis of Maximum Inundation Depths and Flow Velocities The coastline can be approximated in behavior by the use of one-dimensional linear transects of a composite bathymetric and/or topographic profile. The tsunami inundation design parameters of inundation depth and flow velocities are determined by an energy analysis approach. In the Energy Grade Line Analysis, hydraulic analysis using Manning's coefficient for equivalent terrain macroroughness is used to account for friction, along with the profile comprised of a series of one-dimensional slopes, to determine the variation of depth and velocity-associated inundation depth across the inland profile. Velocity is assumed to be a function of inundation depth, calibrated to the prescribed Froude number, $u/\sqrt{gh}$, at the shoreline and decreasing inland. As noted in Kriebel et al. (2017), a Froude number is prescribed in the Energy Grade Line Analysis (EGLA) as a conservative means to determine the magnitudes of u_{max} and h_{max}, but which in reality rarely occur simultaneously. Hence the Froude number value used within the EGLA does not represent the actual Froude number of the flow at the site, which should instead be determined using the flow depth and corresponding velocity from Figure 6.8-1 for the load case being considered. For example, the design Froude number for Load Case 2 when h is 2/3 of h_{max} will be 22% greater than the Froude number prescribed for use within the EGLA. The specified incremental horizontal distance maximum spacing of 100 ft (30.5 m) is necessary for accuracy of the hydraulic analysis.

The Energy Grade Line Analysis is based on rational hydraulic principles for a one-dimensional transect flow assumption, so it is not the same analysis technique as performed by a two-dimensional (2D) flow numerical simulation. The Energy Grade Line Analysis is simple and it is inherently less precise, but is statistically conservative for use as a practical design tool that can be performed by the engineer. One additional conservatism is to use the actual roughness of the terrain in the energy method rather than a "bare-earth" assumption. Also the parameters of "maximum" depth and flow speed are associated with the prescriptive load cases that define the combinations derived from these "maximum" flow parameters. When the actual roughness of the terrain is used in the energy method, it takes a greater initial energy at the shoreline in order to reach the runup. Therefore, conceptually, the energy at the shoreline in the prescriptive method is implicitly greater than the energy value used in the 2D inundation model run on "bare earth." The benefit of this approach is that it produces conservative design values and it implicitly accounts for flow amplification that occurs through the built environment (which the standard 2D inundation model technique does not consider). The 328 ft (100 m) depth is where the waveform based on Probabilistic Tsunami Hazard Analysis can be regionally characterized along the coastline. The Tsunami Design Zone Maps of this standard have been developed from a Probabilistic Tsunami Hazard Analysis (PTHA) using the NOAA Pacific Marine Environmental Laboratory (PMEL) Short-Term Inundation Forecasting for Tsunamis (SIFT), Method of Splitting Tsunamis (MOST), and Community Model Interface for Tsunamis (ComMIT) model for the 2D inundation analysis. The Tsunami Design Zone Maps have been produced to ensure that the inundation limit and runup elevation and the extent of the hazard zone are generally not underestimated (Montoya et al. 2017). The Energy Grade Line Analysis uses this input so that the flow characteristics at the site are not severely underestimated for design purposes. The statistical level of conservatism has been verified by doing many thousands of simulations to compare the energy method with time history outputs from the primary types of numerical inundation models.

The Energy Grade Line Analysis stepwise procedure consists of the following steps:

1. Obtain the runup and inundation limit values from the Tsunami Design Zone Map generated by the ASCE Tsunami Design Geodatabase. Determine the value of α in accordance with Sections 6.6.2 and 6.6.4.
2. Approximate the principal topographic transect by a series of x–z grid coordinates defining a series of segmented slopes, in which x is the distance inland from the shoreline to the point and z is the ground elevation of the point. The horizontal spacing of transect points should be less than 100 ft (30.5 m), and the transect elevations should be obtained from a topographic Digital Elevation Model (DEM) of at least 33 ft (10 m) resolution.
3. Compute the topographic slope, ϕ_i, of each segment as the ratio of the increments of elevation and distance from point to point in the direction of the incoming flow.
4. Obtain the Manning's coefficient, n, from Table 6.6-1 for each segment based on terrain analysis.
5. Compute the Froude number at each point on the transect using Equation (6.6-3).

   Start at the point of runup with a boundary condition of $E_R = 0$ at the point of runup.

   i. Per Section 6.6.1, where the maximum topographic elevation along the topographic transect between the shoreline and the inundation limit is greater than the runup elevation, use a runup elevation that has at least 100% of the maximum topographic elevation along the topographic transect.*
6. Select a nominally small value of inundation depth [~0.1 ft (0.03 m)] $h_r$at the point of runup.
7. Calculate the hydraulic friction slope, s_i, using Equation (6.6-2).
8. Compute the hydraulic head, E_i, from Equation (6.6-1) at successive points toward the shoreline.
9. Calculate the inundation depth, h_i, from the hydraulic head, E_i. Using the definition of Froude number, determine the velocity u. Repeat through the transect until the h and u are calculated at the site.

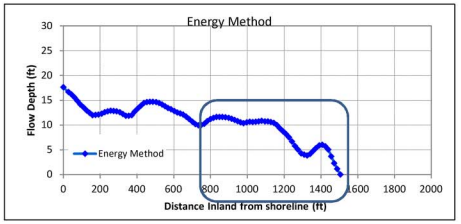
		$\Delta x_i = x_{(i-1)} - x_i$	$\Delta z_i = z_{(i-1)} - z_i$	$\varphi_i = (z_{i-1} - z_i) / \Delta x_i$ input by segment		$\alpha(1 - x_i/x_R)^{1/2}$							

The Energy Grade Line Analysis stepwise procedure consists of the following steps:

1. Obtain the Runup and Inundation Limit values from the Tsunami Design Map — Determine the value of α in accordance with Section 6.6.2 and 6.6.4.
2. Approximate the principal topographic transect by a series of X-Z grid coordinates defining a series of segmented slopes;
   x is the distance inland from the shoreline to the point and z is the ground elevation of the point
3. Compute the topographic slope , φ_i, of each segment as the ratio of the increments of elevation and distance from point to point in the direction of the incoming flow.
4. Obtain the Manning's coefficient, n , from Table 6.6-1 for each segment based on terrain analysis.
5. Compute the Froude number at each point on the transect using **Equation 6.6-3**.
6. Start at the point of Runup with a boundary condition of E_R =0 at the point of runup.
7. Select a nominally small value of inundation depth (~0.1 ft.) h_R at the point of runup.
8. Calculate the hydraulic friction slope , s_i , using **Equation 6.6-2.**
9. Compute the hydraulic energy head E_i from at successive points towards the shoreline.
10. Calculate the inundation depth h_i from the hydraulic energy E_i .
11. Using the definition of the Froude number, determine the velocity u_i .
12. Repeat through the transect until the h and u are calculated at the site.
13. Then, at locations along the transect where the slope ϕi is negative, the velocity determined in accordance with Eq. (6.6-3) shall be increased to account for downslope acceleration.
14. Check that all velocity values are not less than the minimum flow velocity required by Section 6.6.1.
15. The final values are used as the maximum inundation depth, hmax, and the maximum velocity, umax, along the transect



Load Cases based on these parameters are defined in **Section 6.8.3.1.**

Figure C6.6-2. Example transect using the Energy Grade Line Analysis.

10. At locations along the transect where the slope ϕ_i is negative, the velocity determined in accordance with Equation (6.6-3) shall be subsequently increased to account for downslope acceleration, using an amount Δu_i equal to the value calculated per Equation (6.6-4) or 6 ft/s (1.83 m/s), whichever is less.
11. Check that all velocity values are not less than the minimum flow velocity and not greater than the maximum flow velocity required by Section 6.6.1.
12. The final values are used as the maximum inundation depth, h_{max}, and the maximum velocity, u_{max}, along the transect.

*Where Inundation Depth Points are provided in the ASCE Tsunami Design Geodatabase for completely overwashed areas, where the tsunami flows over an island or peninsula into a second water body, the horizontal distance of the inundation limit shall be taken to be the length of the overwashed land. There are two modifications of Section 6.6.1 given for this case, relating to (a) the initial conditions of nonzero depth and velocity at the inland edge of the overwashed area, and (b) the Froude number profile that follows a linear interpolation with distance across the overwashed land. To complete the analysis, the inundation elevation profiles are adjusted so that the computed inundation depths are at least the depths specified at the Inundation Depth Points. The adjusted inundation elevation profile should not be lower than the topographic elevation transect. An example is given in Figure C6.6-3.

Load cases based on these parameters are defined in Section 6.8.3.1. The inundation elevation is also determined from the inundation depth plus the ground elevation.

The Energy Grade Line Analysis algorithm and an example calculation for a portion of a transect follows in Figures C6.6-1 and C6.6-2.

The effects of any sea level rise are to be added to the inundation depth results of the Energy Grade Line Analysis, per Section 6.5.3.

C6.6.3 Terrain Roughness Terrain macroroughness is represented by Manning's coefficient (Kotani et al. 1998, Shimada et al. 2003). Note that for the Energy Grade Line Analysis, a higher value of roughness is conservative because it requires a greater incident energy budget (of $h_0 + U_0^2/2g$) to overcome the frictional losses in reaching the given runup elevation. For site-specific inundation analysis to calculate the runup elevation and inundation limit, the opposite is true, in that lower friction allows the inundation to reach a higher point.

Table 6.6-1 provides values of Manning's coefficient, n, based on land use to represent equivalent roughness. Where an area is predominantly light-frame residential houses, which will not resist tsunami flow, it is advisable to use the coefficient of roughness for "all other cases." Where building obstructions are enclosed structures of concrete, masonry, or structural steel construction, Aburaya and Imamura (2002) and Imamura (2009) indicate that n varies with the coverage density of such buildings expressed as a coverage percentage, θ, their width, w, and the inundation depth, D, in accordance with

$$n = \sqrt{n_0^2 + \frac{C_D}{2gw} \times \frac{\theta}{100-\theta} \times D^{4/3}}$$

where n_0 is 0.025 and C_D is 1.5. In general, values of n greater than 0.040 result where the urban density, θ, is greater than 20%. For densities of 80% or more, values of n can approach 0.10.

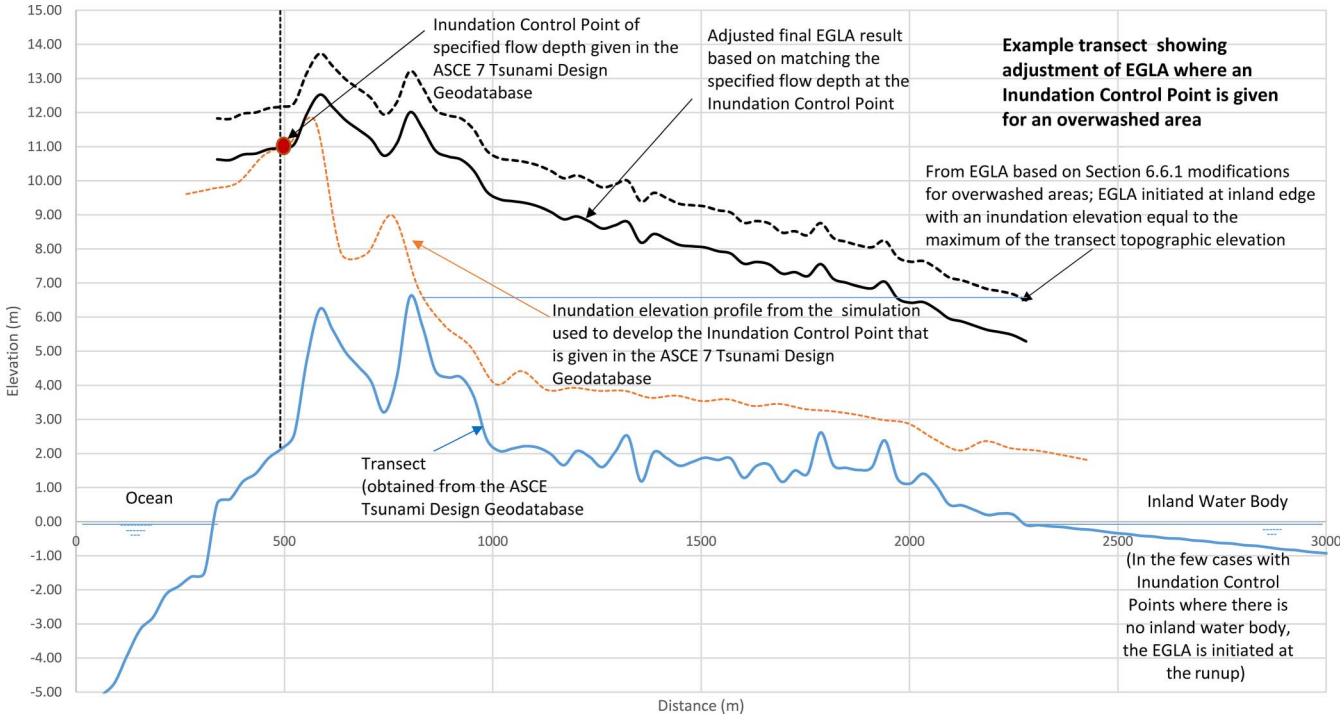

Figure C6.6-3. Example Energy Grade Line Analysis (EGLA) with adjustment where an inundation depth point is specified in the ASCE Tsunami Design Geodatabase.

@seismicisolation

Studies by the Tsunami Loads and Effects Subcommittee indicate that it is not necessary to use values of Manning's roughness greater than 0.050 in the Energy Grade Line Analysis. Values of n greater than 0.050 result in much higher statistical conservatism in calculated momentum flux by the Energy Grade Line Analysis, compared to numerical solutions.

C6.6.4 Tsunami Bores The criteria for the occurrence of bores consist of a complex interaction of the tsunami waveform and the coastal bathymetry, which can be determined through site-specific inundation numerical modeling. One such condition described in the literature arises where soliton fission waves are generated by shoaling over a long bathymetric slope of approximately 1/100 or milder (Murata et al. 2010, Madsen et al. 2008). These packets of shorter-period waves on the front face of the long-period tsunami then break into a series of bores where the soliton amplitude over depth ratio reaches 0.78 to 0.83. Another case occurs where a shoaling tsunami encounters an abruptly rising seabed floor, such as a fringing shallow reef.

C6.7 INUNDATION DEPTHS AND FLOW VELOCITIES BASED ON SITE-SPECIFIC PROBABILISTIC TSUNAMI HAZARD ANALYSIS

A method of Probabilistic Tsunami Hazard Analysis has been established in the recognized literature that is generally consistent with Probabilistic Seismic Hazard Analysis in the treatment of uncertainty.

The basics of Probabilistic Tsunami Hazard Analysis for a region are as follows:

1. Tsunamigenic subduction zones and nonsubduction seismic thrust faults are discretized into a compiled system of rectangular subfaults, each with corresponding tectonic parameters.
2. Tsunami waveform generation is modeled as a linear combination of individual tsunami waveforms, each generated from a particular subfault, with a set sequence of subfaults used to describe the earthquake rupture in location, orientation, and rupture direction and sequence.
3. A statistically weighted logic tree approach is used to account for epistemic uncertainties in the tectonic parameters. The logic tree model parameters are developed from available tectonic, geodetic, historical, and paleotsunami data and estimated plate convergence rates. A probability distribution is used to account for aleatory uncertainties (i.e., intrinsic variability in each actual earthquake event).
4. Each individual tsunami waveform is propagated in deep water to 328 ft (100 m) depth using linear long-wave equations to take into account spatial variations in seafloor depth. This set of precomputed individual tsunami waveforms is combined in a linear fashion (i.e., Green's function approach) for subsequent analysis.
5. At the 328 ft (100 m) depth, determine the highest offshore wave heights and develop wave height, period, and waveform parameters for the design level exceedance of the 2,475-year tsunami event. The still-water level may be considered to be at the Reference Sea Level for this purpose.
6. Disaggregate (i.e., separate out for use in subsequent analysis) the seismic sources and associated moment magnitudes that together contribute at least 90% to the net offshore tsunami hazard at the site under consideration for the design level mean recurrence interval.
7. Use nonlinear shallow-water wave equations to transform each disaggregated tsunami event, or the Hazard-Consistent Tsunami event(s) (see following) from 328 ft (100 m) depth toward the shore to determine the associated maximum inundation.
8. Analyze each tsunami event from the disaggregated sample to determine flow parameters for the site of interest. Manning's coefficient for equivalent terrain macroroughness is used to account for friction. Maximum runup, inundation depth, flow velocity, and/or specific momentum flux at the site of interest are permitted to be evaluated by either of the following techniques.
   (a) Determine the Hazard-Consistent Tsunami as one or more surrogate events that replicate the weighted average waveform corresponding to the offshore wave height for the return period. The inundation limit for the Hazard-Consistent Tsunami shall match the area that is inundated by tsunami waves from all the disaggregated major source zones for that particular return period. Flow parameters at the site of interest shall be determined from the Hazard-Consistent Tsunami waveform.
   (b) Develop the probabilistic distributions of flow parameters from the disaggregated sample of computed tsunamis and construct the statistical distributions of flow parameters for at least three critical load cases.
9. From the probabilistic events, capture the design flow parameters of inundation depth, flow velocity, and/or specific momentum flux at the site of interest.

Data referenced in Section 6.7 are provided by ASCE. The ASCE Tsunami Design Geodatabase is version-specific for the application of each edition of ASCE 7, and the user of the standard should take care to select the proper data set as appropriate for the building code adopted by the jurisdiction.

The ASCE Tsunami Design Geodatabase of geocoded reference points of offshore 328 ft (100 m) depth; Tsunami Amplitude, H_T; and predominant wave period, T_{TSU}, of the Maximum Considered Tsunami are available at http://asce7tsunami.online, including the following data sets:

- Offshore tsunami amplitude with predominant period, and
- Disaggregated hazard source contribution figures.

Because actual and model-simulated offshore wave amplitude time histories are not exhibited as pure signals with a singular wave period, a procedure was used to capture a practical equivalent period that would be representative of the Offshore Tsunami Amplitude. To determine half of the predominant wave period, the following steps were performed. First, the zero-crossings immediately before and after the maximum Offshore Tsunami Amplitude were found. If there was no zero-crossing before the maximum amplitude, as might be the case for a leading-elevation tsunami waveform, then the start time of the time series was considered as the first zero-crossing time. Next, the total area in the tsunami elevation time series between the two zero-crossing times was integrated. The half-period is the time between the point when 5% of the total area has passed and the point when 95% of the total area has passed.

The GIS digital map layers for probabilistic subsidence are available in the ASCE Tsunami Design Geodatabase at http://asce7tsunami.online.

An example of the ASCE Tsunami Design Geodatabase of Offshore Tsunami Amplitude, predominant wave period, and geocoded location of a database point is shown in Figure C6.7-1(a). An illustration of the derivation of the predominant wave period, T_{TSU}, is shown in Figure C6.7-1(b).

@seismicisolation

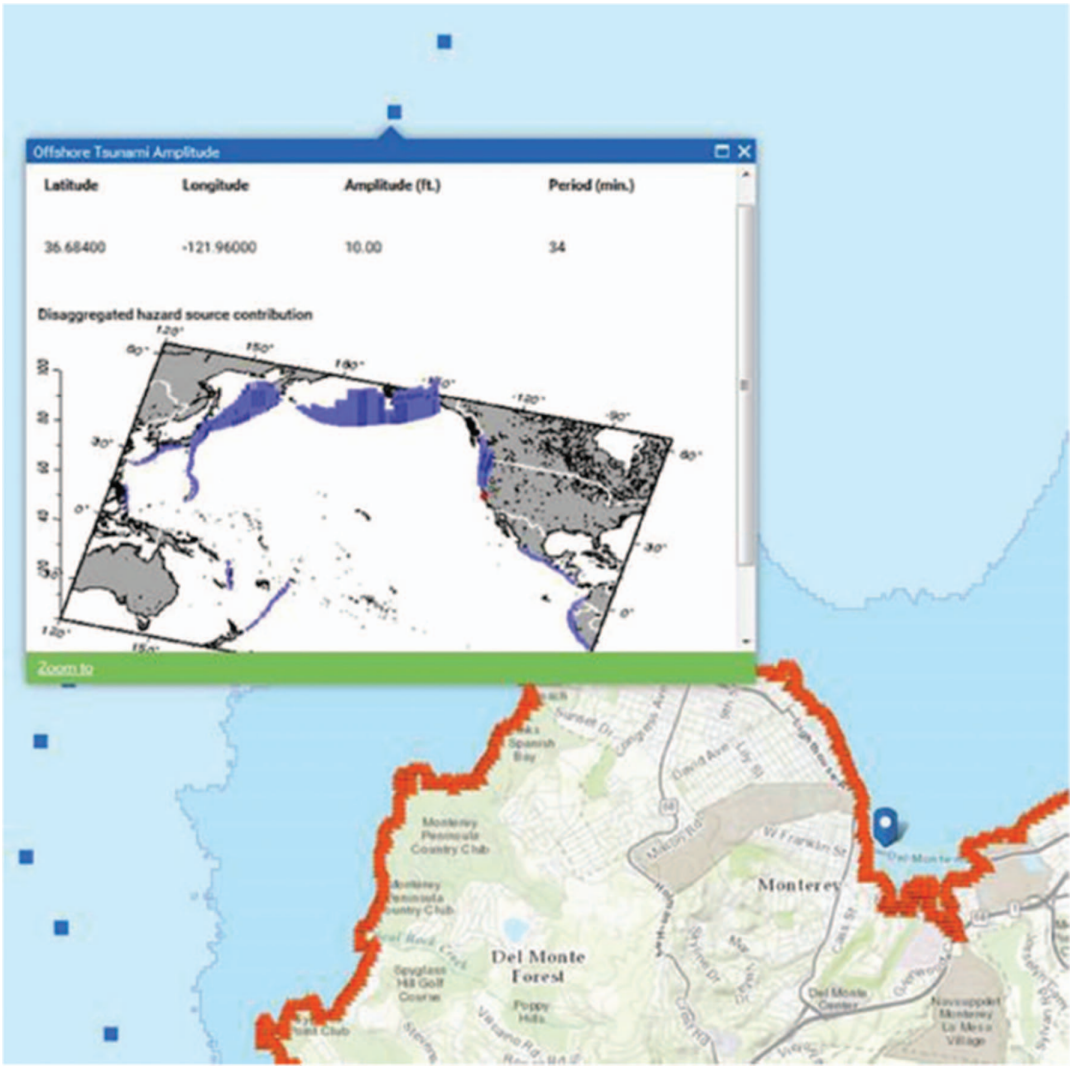

Figure C6.7-1(a). Example of the Offshore Tsunami Amplitude from the ASCE Tsunami Design Geodatabase (amplitude in feet, period in minutes).

C6.7.1 Tsunami Waveform The waveform prescribed here is a sum of a series of soliton pairs, with each pair composed of one with a positive and one with a negative amplitude. These pairs reflects (1) the case where the leading wave has a positive amplitude, and (2) the case where the largest (positive) amplitude wave follows a large trough wave. Because tsunamis consist of multiple waves interacting with the coastal bathymetry, both cases of leading or trailing depression waveforms are to be considered. The total number of soliton pairs to be included in the offshore tsunami waveform is given by the parameter N. As shown in tsunami observations and tsunami simulations, the value of N is dependent on whether the tsunami is from a local earthquake source or from a distant earthquake source, and therefore different values of N are prescribed for different regions, as given in Table 6.7-1. The range of parameter a_2 shall also be considered in developing the suite of waveforms to be analyzed by inundation modeling. The parameters a_1, a_2, and T_{TSU} can be obtained from the map (Figure 6.7-1) or from Table 6.7-1, which provides a more regionalized model based on Figure 6.7-1. The values in Table 6.7-1 were compiled from a series of scenarios modeled for each of the five western states, in which the maxima of the offshore wave amplitudes of the crest and trough were sampled at offshore locations at 328 ft (100 m) depth.

C6.7.2 Tsunamigenic Sources Tsunamigenic sources that affect the Pacific states have been identified through historical records as well as systematic modeling of all circum-Pacific subduction zones. Maximum magnitudes were derived from perceived maximum dimensions for future earthquake ruptures and scaling relations between dimensions and magnitude. In the Salish Sea of Washington State, the ASCE Tsunami Design Geodatabase has been probabilistically analyzed from a hazard-consistent source in the Cascadia Subduction Zone together with local thrust sources that include the Seattle Fault, the Tacoma Fault, and the Rosedale-Dominant Tacoma Fault, with source parameters described in Venturato et al. (2007), and other local tsunamigenic sources, such as the South Whidbey Island and Darrington-Devils Mountain Faults, that are considered potentially significant.

In Alaska, local tsunami inundations are based on suites of hypothetical earthquake scenarios and landslide scenarios modeled by the Alaska Division of Geological & Geophysical

@seismicisolation

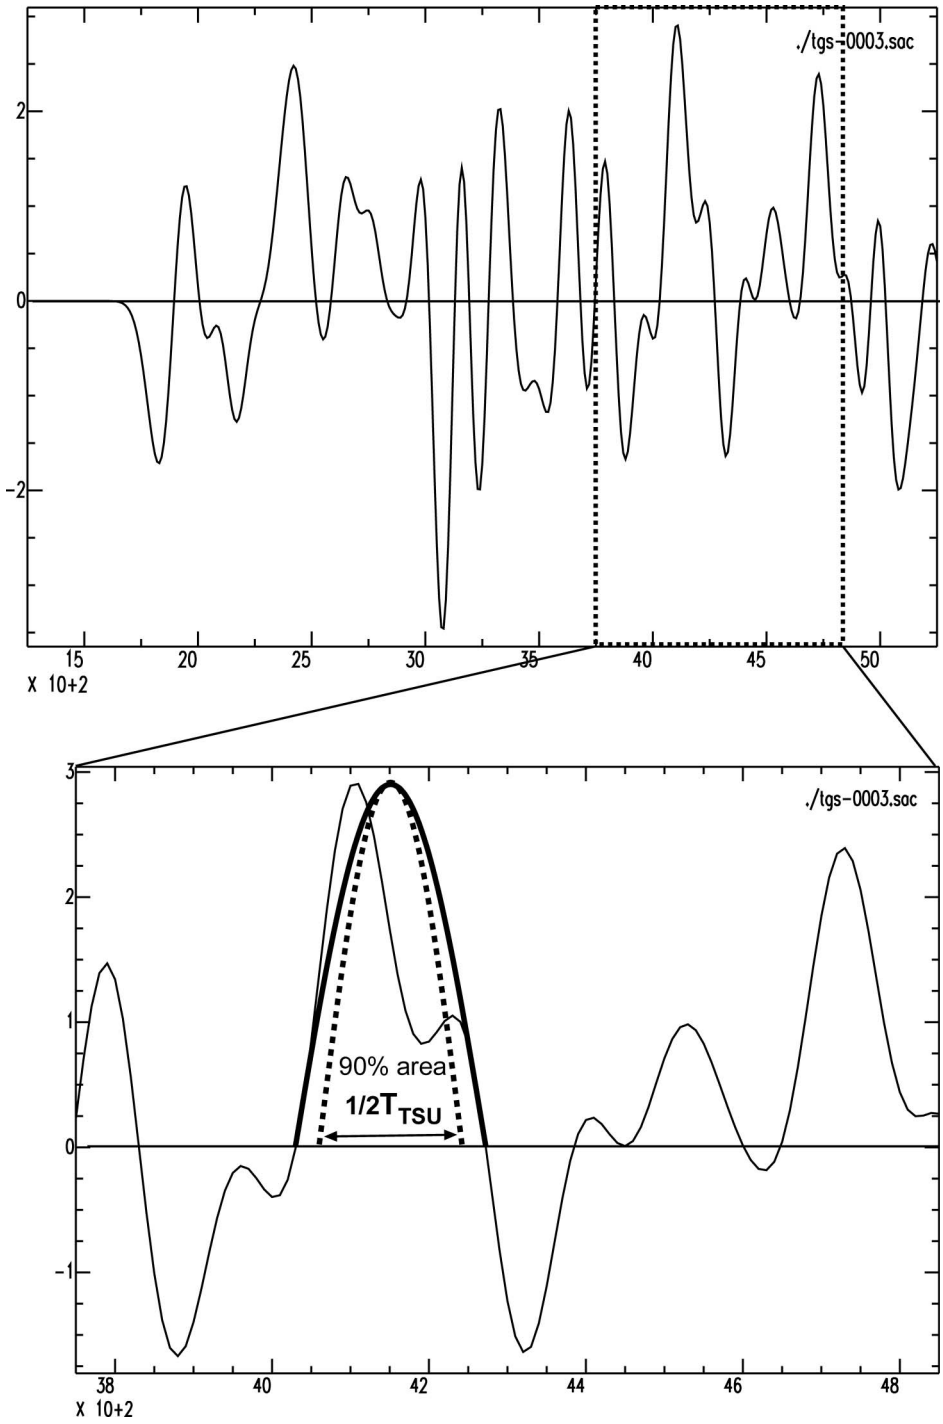

Figure C6.7-1(b). Illustration of the predominant wave period, T_{TSU}, of the offshore tsunami waveform.

Surveys for Elfin Cove, Gustavus, Haines, Homer, Hoonah, Juneau, Seldovia, Seward, Skagway, Valdez, Whittier, and Yakutat (Suleimani et al. 2010, 2015, 2016, 2018; Nicolsky et al. 2011, 2017, 2018). Because each of these maps is based on several hypothetical tsunamis of tectonic and landslide origins, none of which is the result of Probabilistic Tsunami Hazard Analysis, they do not constitute a design basis for the ASCE 7 standard and are not included in the ASCE Tsunami Design Geodatabase. The referenced reports state that "the limits of inundation shown should only be used as a guideline for emergency planning and response action," and that "these results are not intended for land-use regulation." Therefore, the ASCE Tsunami Design Geodatabase does not include any landslide-induced tsunami inundation. Nevertheless, tsunamis generated by subaerial or submarine slope failures can pose significant hazards in the fjords of coastal Alaska and other high-latitude fjord coastlines.

C6.7.3 Earthquake Rupture Unit Source Tsunami Functions for Offshore Tsunami Amplitude For the computation of offshore amplitudes [e.g., at the 328 ft (100 m) depth contour], the principle of linearity is used to compute tsunami waves as a

@seismicisolation

summation of precomputed waves for smaller subsources, which in total make up the intended earthquake rupture.

C6.7.4 Treatment of Modeling and Natural Uncertainties *Aleatory* uncertainty is the uncertainty that arises because of unpredictable variability in the performance of the natural system being modeled. *Epistemic* uncertainty is the uncertainty that arises because of lack of knowledge of the physical mechanism of the natural system being modeled. Typically, aleatory uncertainties are represented in probabilistic analysis in the form of probability distribution functions, whereas epistemic uncertainties are included in the form of (weighted) alternative logic tree branches. The technique for a one-sigma allowance is specified in order that numerical modeling provides a Hazard-Consistent Tsunami waveform that accounts for uncertainty in tsunami amplitude. It is a key component of Probabilistic Tsunami Hazard Analysis to include a reliability factor.

C6.7.5 Offshore Tsunami Amplitude The 328 ft (100 m) depth contour was chosen because tsunami waves behave linearly in deeper water, which allows for rapid calculation of tsunami waveforms, which enables a comprehensive probabilistic approach. The 328 ft (100 m) depth was selected to minimize the amount of nonlinear shoaling caused by such things as the Nearshore Profile, embayment amplification, and resonance effects. The Offshore Tsunami Amplitude at this reference depth represents with more clarity the probabilistic tsunami amplitude values for an area that do not vary dramatically parallel to the shoreline. To use a fully shoaled tsunami wave amplitude at the shoreline would result in more difficulty in verifying or calibrating whether other site-specific models have actually used a Hazard-Consistent Tsunami because the waveform has become more complex at the shoreline, and in certain cases it may have broken into a series of bores; for these reasons, the tsunami amplitudes have large spatial variation in the nearshore regime. It would also not be possible at the shoreline to specify regional waveform parameters, such as in Table 6.7-1 at the 328 ft (100 m) depth, that would be valid in all nearshore regimes. The Offshore Tsunami Amplitude and associated parameters of Section 6.7 are calibrated to the 2,475-year hazard level, and the primary purpose of this information is to support site-specific inundation analysis of Tsunami Risk Category IV structures, where more detailed spatial bathymetry and topography are used with a 2D inundation model software code to develop flow parameters at the site. It is called a 2D model because the third vertical dimension of flow speed is depth-averaged, but it uses a 3D spatial digital raster representation of the terrain.

C6.7.5.1 Offshore Tsunami Amplitude for Distant Seismic Sources An efficient way to compute probabilistic tsunami exceedance amplitudes is by precomputing tsunami time series (Green's functions) for a suite of subsources with unit slip (e.g., 3.28 ft or 1 m) that together can be used to represent actual slip distribution on a larger fault. The resultant tsunami time series is then a summation of the individual Green's functions, which are each multiplied by the actual slip relative to the unit slip for each subsource. Examples of this process are given in Thio et al. (2010) and Gica et al. (2008). The Site-Specific Probabilistic Tsunami Hazard Analysis is validated by comparison to the Offshore Tsunami Amplitudes given by the ASCE Tsunami Design Geodatabase. This validation includes individual matching to at least 80% of the reference amplitude values and matching of the mean of the computed offshore tsunami amplitudes to at least 100% of the mean of the reference amplitude points. The extent of offshore tsunami amplitudes to be computed and validated requires a sufficient number of points to represent the region most influential on the resulting inundation at the site.

Application of this requirement to islands where the projected width is less than 40 mi (64.4 km) would require matching offshore wave amplitudes simultaneously on more than one side of the island. This could result in unintended influence of an inappropriate tsunami source. The extent of offshore tsunami amplitudes is therefore shown in Section 6.7.5.1.4(d) to match the projected width of the island.

At certain locations it may be necessary to generate sources based on an extent of offshore tsunami amplitude points that is less than those required by Sections 6.7.5.1.4(a) and 6.7.5.1.4(b). Examples include coastal geometries where tsunami waves induce resonance, where tsunami waves wrap around to the lee of an island, or where wave reflection between islands, or between an island and adjacent coastline, affects the wave amplitudes. The islands of Hawaii exhibit such conditions, where a 10 mi (16.1 km) extent was determined to be appropriate. Where such circumstances are demonstrated, use of shorter extents of offshore tsunami amplitude points is permitted, subject to peer review by an appropriately qualified tsunami modeler.

C6.7.5.2 Direct Computation of Probabilistic Inundation and Runup For local sources, it is necessary to compute a suite of scenarios, which represent a probabilistic distribution, taking into account aleatory uncertainties in such things as slip distribution, magnitudes, and tide levels. Ground subsidence should be taken into account in the actual tsunami calculations. The surface deformation can be computed using a variety of algorithms that compute the elastic response of a medium caused by slip on a fault.

C6.7.5.3 Use of Higher-Order Tsunami Model Features Tsunami models may have the capability to use higher-order features that may affect the propagation of a tsunami. These features are considered to be secondary enhancements to the leading-order, shallow-water wave equations (e.g., Titov and Synolakis 1998) commonly used for tsunami modeling. Such higher-order features, as discussed in Baba et al. (2017), provide refinement in the tsunami arrival time and shape of the incoming waves, with the inclusion of earth elasticity, seawater density stratification, and dispersion yielding the most significant accuracy increase. There will generally be greater spatial variability in the amplitudes of the tsunami waves generated by such a higher-order model. For example, it has been shown that with the same tsunami source event, dispersion of waves can lower or raise the computed maximum offshore amplitudes around Hawaii by 50% (Bai and Cheung 2016, Kirby et al. 2013, Bai et al. 2018), with the pattern strongly dependent on the location and size of the earthquake source.

Given that the Offshore Tsunami Amplitudes in the ASCE Tsunami Design Geodatabase were generated using a model which solves the leading-order, shallow-water wave equations without such higher-order features, independent peer review is required to ensure that the tsunami inundation resulting from the use of higher-order model features is consistent with the probabilistic hazard level of this chapter. In addition, the peer reviewer should verify that the statistical aleatory uncertainty factor in the hazard level of the model results is consistent with the reliability target parameters associated with the Offshore Tsunami Amplitude hazard, as given in Chock et. al. (2016).

@seismicisolation
@seismicisolation

C6.7.6 Procedures for Determining Tsunami Inundation and Runup

C6.7.6.1 Representative Design Inundation Parameters These parameters have been shown to be relevant for the estimation of different types of tsunami impact.

C6.7.6.2 Seismic Subsidence before Tsunami Arrival The uplift and subsidence during an earthquake that generates a tsunami also causes vertical changes to the coastal topography, and this change needs to be taken into account for modeling local tsunamis directly from the source. The effect of seismic subsidence follows the recognized deformation model of Okada (1985) illustrated in Figure C6.7-2. The subsidence can be considered instantaneous, and it occurs before the arrival of the tsunami waves. Figure 6.7-3 is the 2,475-year subsidence map, which also identifies which areas are governed by the local coseismic tsunami source. For ASCE 7-22, models with improved fault geometry were used in the probabilistic analysis for a more accurate subsidence map for Northern California, Oregon, and Washington. Because the map shows probabilistic subsidence consistent with the Probabilistic Tsunami Hazard Analysis logic tree, values cannot be directly compared with the tectonic movements resulting from specific earthquake scenarios. Section 6.7.6.2 allows the use of the subsidence shown in Figure 6.7-3 as implemented in the ASCE Tsunami Design Geodatabase, or the subsidence computed from the fault rupture mechanism associated with a Hazard-Consistent Tsunami site-specific scenario. Inundation Depth Points in the Geodatabase for overwashed Tsunami Design Zones refer to the local flow depth taking into account the modeled subsidence. Southern California and Hawaii are not adjacent to interplate subduction zones, so they are not subject to regional seismic ground subsidence before a tsunami.

C6.7.6.3 Model Macroroughness Parameter The effects of ground friction on tsunami inundation are significant and need to be considered. There are different techniques in which ground friction is incorporated in numerical schemes; the most common is the Manning's coefficient. If other approaches are used, care should be taken so that they closely follow the effect related to the appropriate Manning's coefficient.

C6.7.6.4 Nonlinear Modeling of Inundation Typically in numerical tsunami modeling, the equations solved correspond to the shallow-water approximation, with nonlinear effects such as inundation (moving boundary), bottom friction, and advection. Usually, these algorithms solve the equations of motion in two (horizontal) dimensions, with the vertical properties averaged over depth. Most of the effects mentioned here are taken into account, provided that an acceptable tsunami inundation model is used. Dispersion is taken into account in some approaches (Boussinesq-type); dispersion is required for the modeling of small dimensional sources, such as submarine landslides. Bore formation is more accurately modeled with algorithms that preserve momentum. In the case of local tsunamis, where the bore formation is particularly pronounced, these algorithms are preferred over approaches that do not explicitly conserve mass.

C6.7.6.5 Model Spatial Resolution Tsunami Digital Elevation Models for the United States are available from NOAA at http://www.ngdc.noaa.gov/mgg/inundation/. For select areas, models with resolutions of up to 32.8 ft (10 m), or 1/3 arcsec, are available as of 2015.

C6.7.6.6 Built Environment The standard practice of all tsunami inundation models is to use a low Manning's roughness parameter for the topography so that the lines for the inundation limit and runup elevation are not underestimated. The models have also been numerically benchmarked with that assumption against analytical and laboratory cases with smooth profiles. Digital Elevation Models (DEMs) for very high-resolution modeling may be available in the form of lidar (light detection and ranging) models from federal, state, county, or city agencies, or from local site surveys. In some

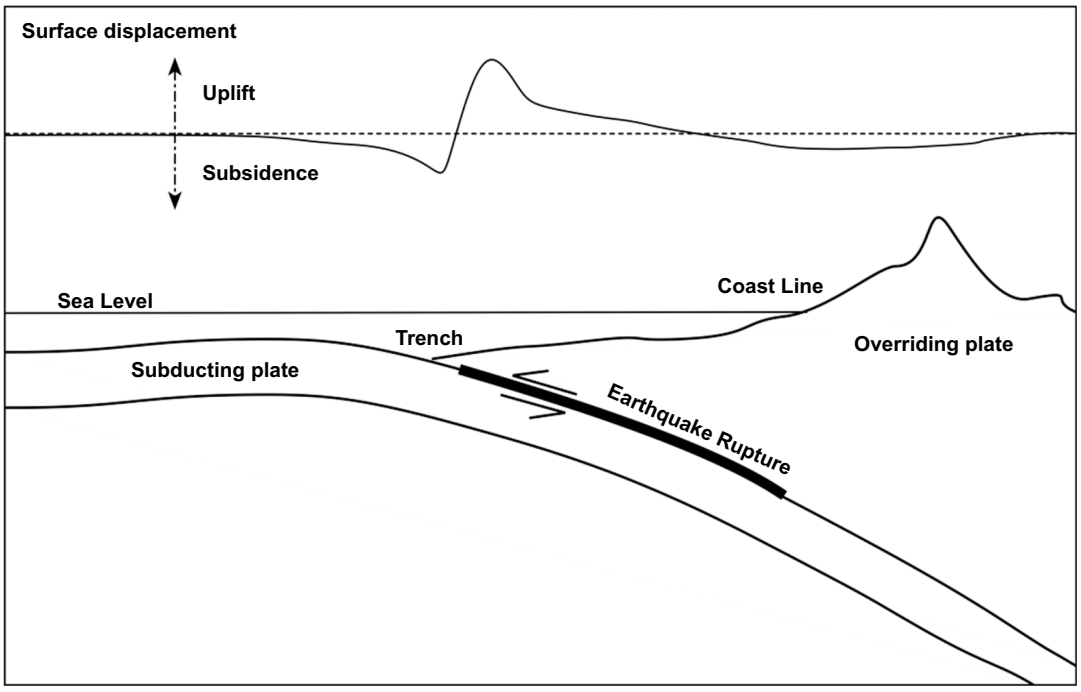

Figure C6.7-2. Subduction zone earthquake mechanism for tsunami generation.

@seismicisolation

cases, the built environment has been removed from the lidar images, which negates their usefulness for detailed inundation modeling. When the built environment is modeled as fixed bluff bodies on the terrain, it is appropriate to include only those with sufficient structural resilience to resist tsunami forces.

C6.7.6.7 Inundation Model Validation The National Tsunami Hazard Mitigation Program (NTHMP) (2012) has developed a number of benchmarking exercises that include analytical, laboratory, and real-world simulations, available at the Forecast Propagation Database (http://nctr.pmel.noaa.gov/propagation-database.html). Aida (1978) provides further information relating to the degree-of-fit criteria of K between 0.8 and 1.2 and κ less than 1.4.

C6.7.6.8 Determining Site-Specific Inundation Flow Parameters The Hazard-Consistent Tsunami is a term of craft used to refer to a means to replicate the effects of the Maximum Considered Tsunami (MCT) hazard level by one or more surrogate scenarios. Hazard-Consistent Tsunamis are devised to incorporate the net effect of an explicit analysis of uncertainty in the parameters originally used in determining the MCT through conducting the Probabilistic Tsunami Hazard Analysis. To incorporate this aleatory uncertainty in a few surrogate Hazard-Consistent Tsunamis, the slip parameters of the generating rupture of the Hazard-Consistent Tsunami are increased. This is a procedural device to produce a convenient representation of input for a more limited number of inundation analyses. As a result, the Hazard-Consistent Tsunami appears greater than a single deterministic event generated by an earthquake of that mean recurrence interval at the same source.

In urban environments, the flow velocities determined by a site-specific inundation analysis for a given structure location may not be taken as less than 90% of those determined in accordance with the Energy Grade Line Analysis method. For other terrain roughness conditions, the site-specific inundation analysis flow velocities at a given structure location shall not be taken as less than 75% of those determined in accordance with the Energy Grade Line Analysis method. These restrictions apply before any velocity adjustments caused by flow amplification. The reason for these restrictions is that the tsunami model validation standard (Synolakis et al. 2007) presently does not validate flow velocities, and the committee's evaluation indicated that in certain cases of field observations, some inundation models appear to underestimate flow velocities. The limiting values are based on a reliability analysis accounting for the reduced uncertainty of momentum flux associated with site-specific probabilistic tsunami hazard inundation analysis, compared to the prescriptive Energy Grade Line Analysis method based on the ASCE 7 Tsunami Design Zone Maps (Chock et al. 2016).

C6.7.6.9 Tsunami Design Parameters for Flow over Land The inundation numerical model should capture the time-correlated series of inundation depth and flow velocity (and therefore the representation of momentum flux) at the site for the three key load cases defined in Section 6.8.3.1. However, if the maximum momentum flux is found to occur at an inundation depth different from Load Case 2, that point in the time series should also be considered.

C6.8 STRUCTURAL DESIGN PROCEDURES FOR TSUNAMI EFFECTS

It is important to understand that building failure modes differ fundamentally between seismic loads (high-frequency dynamic effects generated on the inertial masses of a structure) and tsunami loads (externally and internally applied sustained fluid forces varying with inundation depth over long-period cycles of load reversal). Tsunami-induced failure modes of buildings have been examined in several detailed analyses of case studies taken from the Tohoku tsunami of March 11, 2011 (Chock et al. 2013a). Building components are subject simultaneously to internal forces generated by the external loading on the lateral-force-resisting system, together with high-intensity momentum pressure forces exerted on individual members. Performance objectives for structures subject to tsunami design requirements are given in Table C6.8-1.

C6.8.1 Performance of Tsunami Risk Category II and III Buildings and Other Structures Importantly, when evacuation from the inundation zone before tsunami arrival is not possible because of long evacuation distances, road congestion, or damaged infrastructure, the public will attempt to use taller buildings to escape the tsunami inundation and will inherently expect that such taller structures will not collapse during the tsunami. As just one example from the city of Ishinomaki, per a detailed investigation of the lessons for international preparedness after the 2011 Great East Japan Tsunami (Fraser et al. 2012), about 500 people sought refuge at three designated buildings in Ishinomaki. In addition to the few Tsunami Vertical Evacuation Refuge Structures available, "there was widespread use of buildings for informal (unplanned) vertical evacuation in Ishinomaki on March 11th, 2011. In addition to these three designated buildings, almost any building that is higher than a 2-story residential structure was used for vertical evacuation in this event. About 260 official and unofficial evacuation places were used in total, providing refuge to around 50,000 people. These included schools, temples, shopping centres and housing."

Tsunami Risk Category III buildings and other structures are to be designed against collapse, since these structures include school buildings with mass public assembly occupancies, health-care facilities with 50 or more resident patients, critical infrastructure such as power and water treatment, and facilities that may store hazardous materials (when the quantities of hazardous material do not place them in Risk Category IV). Where the structure does not have an occupiable floor with an elevation exceeding 1.3 times the Maximum Considered Tsunami inundation elevation by more than 10 ft (3.05 m), the facility should implement a plan and procedure for evacuation to a location above and outside of the Tsunami Evacuation Zone or to a designated Tsunami Vertical Evacuation Refuge Structure.

Table C6.8-1. Tsunami Performance Levels per Tsunami Risk Category.

	Tsunami Performance Level Objective		
Hazard Level and Tsunami Frequency	**Immediate Occupancy**	**Damage Control**	**Collapse Prevention**
Maximum Considered Tsunami (2,475-year mean recurrence interval)	Tsunami Vertical Evacuation Refuge Structures	Tsunami Risk Category IV and Tsunami Risk Category III Critical Facilities	Tsunami Risk Category III and Risk Category II

@seismicisolation

C6.8.2 Performance of Tsunami Risk Category III Critical Facilities and Tsunami Risk Category IV Buildings and Other Structures The state, local, or tribal government may specifically designate certain traditionally Risk Category III structures as more important Critical Facilities that have post-tsunami mission-critical functions or have more critical roles in economic recovery. Critical Facilities and Risk Category IV Essential Facilities should be located outside of the Tsunami Design Zone whenever possible. For those structures that necessarily exist to provide critical and essential services to a community within a coastal zone subject to tsunami hazard, the design provisions target better than a Life Safety performance level (that is, what is called the Damage Control performance level) for the floor levels that are not inundated. Vertical Evacuation Refuge Structures have the highest performance level objective. The Damage Control performance level is an intermediate structural performance level between Life Safety and Immediate Occupancy.

C6.8.3 Structural Performance Evaluation

C6.8.3.1 Load Cases The normalized inundation depth and depth-averaged velocity time history curves of Figure 6.8-1 (and corresponding Table C6.8-2) are based on tsunami video analysis, and they are generally consistent with numerical modeling with respect to the load cases defining critical stages of structural loading for design purposes (Ngo and Robertson 2012). Load Case 1 is for calculating the maximum buoyant force on the structure along with the associated hydrodynamic lateral force, the primary purpose of which is to check the overall stability of the structure and its foundation anchorage against net uplift. The uplift force, calculated in accordance with Section 6.9.1, depends on the differential inundation depth exterior to the structure versus the flooded depth within it. Load Case 2 is for calculating the maximum hydrodynamic forces on the structure. Load Case 3 is for calculating the hydrodynamic forces associated with the maximum inundation depth. The time history curves can be used to determine the inundation depth and velocities at other stages of inundation as a function of the maximum values determined by the Energy Grade Line Analysis. When a site-specific inundation analysis procedure is used, the local Authority Having Jurisdiction may approve a site-specific inundation and velocity time history curve, subject to the minimum values of 80% or 100% of the Energy Grade Line Analysis, as indicated.

C6.8.3.2 Tsunami Importance Factors The values of Tsunami Importance Factors are derived from the target structural reliabilities, which were calculated using Monte Carlo simulation involving a million trial combinations of random variables independently occurring in proportion to their statistical distributions for the demand parameters of fluid density, closure ratio, Energy Grade Line Analysis momentum flux, inundation depth hazard, and the aleatory uncertainty of inundation depth. For capacity, the structural component analyzed is a beam-column member carrying gravity loads. The Importance Factors for each risk category, analyzed in combination with the other parameters as discussed, result in structural component reliabilities, given that the MCT has occurred, that are similar to seismic systemic performance given that the maximum considered earthquake (MCE) has occurred:

- Tsunami Risk Category II: A tsunami Importance Factor of 1.0 results in structural component limit state exceedance probability of 7.5% $_{(MCT)}$ versus 10% $_{(MCE)}$ for collapse of the lateral-force-resisting system during an earthquake.
- Tsunami Risk Category III: A tsunami Importance Factor of 1.25 results in structural component limit state exceedance probability of 4.9% $_{(MCT)}$ versus 5% $_{(MCE)}$ for collapse of the lateral-force-resisting system during an earthquake.
- Tsunami Risk Category IV: A tsunami Importance Factor of 1.25 results in structural component limit state exceedance probability of 2.7% $_{(MCT)}$ versus 2.5% $_{(MCE)}$ for collapse of the lateral-force-resisting system during an earthquake.
- The exceedance probability for the limit state of structural components of a Tsunami Vertical Evacuation Refuge Structure given the occurrence of the MCT would be approximately 0.8%.

Section 6.5.2, Tsunami Risk Category IV Buildings and Other Structures, requires that a site-specific Probabilistic Tsunami Hazard Analysis per Section 6.7 be performed, but this requirement has an exception where the inundation depth determined by the Energy Grade Line Analysis (EGLA) is less than 12 ft (3.66 m). The Importance Factors of Section 6.8.3.2 were determined in an analysis described in Chock et al. (2016). Site-specific inundation analysis reduces the uncertainty of the flow depth and velocities. Under the exception where site-specific inundation analysis is not performed, the Importance Factor needs to be greater, since the less accurate parametric EGLA would be used for design. Accordingly, if the engineer does not use a site-specific inundation model analysis for Category IV structures where the inundation depth is less than 12 ft (3.66 m), an Importance Factor of 1.5 is used to achieve equivalent reliability for this exception.

C6.8.3.3 Load Combinations The structural load combinations given are consistent with the Extraordinary Load Combinations of Section 2.5 of this standard by applying F_{TSU} for incoming and receding directions for A_k in the load combinations given in Equation (2.5-1), as modified to include the effect of tsunami-induced lateral earth pressure caused by water seepage through the soil, H_{TSU}, resulting in Equation (6.8-1). The inundation depths and velocities for determining F_{TSU} and H_{TSU} must be consistent at the hazard level of the Maximum Considered

@seismicisolation

Tsunami (MCT). The load factor for H_{TSU} is given as 1.0 because these load combinations occur during the defined submerged conditions of the Maximum Considered Tsunami. The Probabilistic Tsunami Hazard Analysis criteria for determining runup already include explicit mathematical consideration of uncertainty; therefore, no additional factor needs to be applied to the 2,475-year MCT flow characteristics for Risk Category II buildings and other structures.

No allowable stress design load combinations were deemed necessary. When foundation stability analysis is performed for tsunami-induced soil seepage pressures, the results are equivalent to the existing recognized US Army Corps of Engineers (USACE 2005, 2011) specifications for geotechnical limit equilibrium analysis for both overturning and uplift. For foundation design, resistance factors are given in Section 6.12.1.

C6.8.3.4 Lateral-Force-Resisting System Acceptance Criteria The use of the overstrength factor to evaluate the overall lateral-force-resisting system is permitted to be used where the Life Safety performance level is to be verified. If Life Safety criteria have been met, then the Collapse Prevention criteria have also been met as a consequence, which is the minimum requirement for Tsunami Risk Category II and Tsunami Risk Category III buildings and other structures. For Immediate Occupancy, the structural system should be explicitly analyzed.

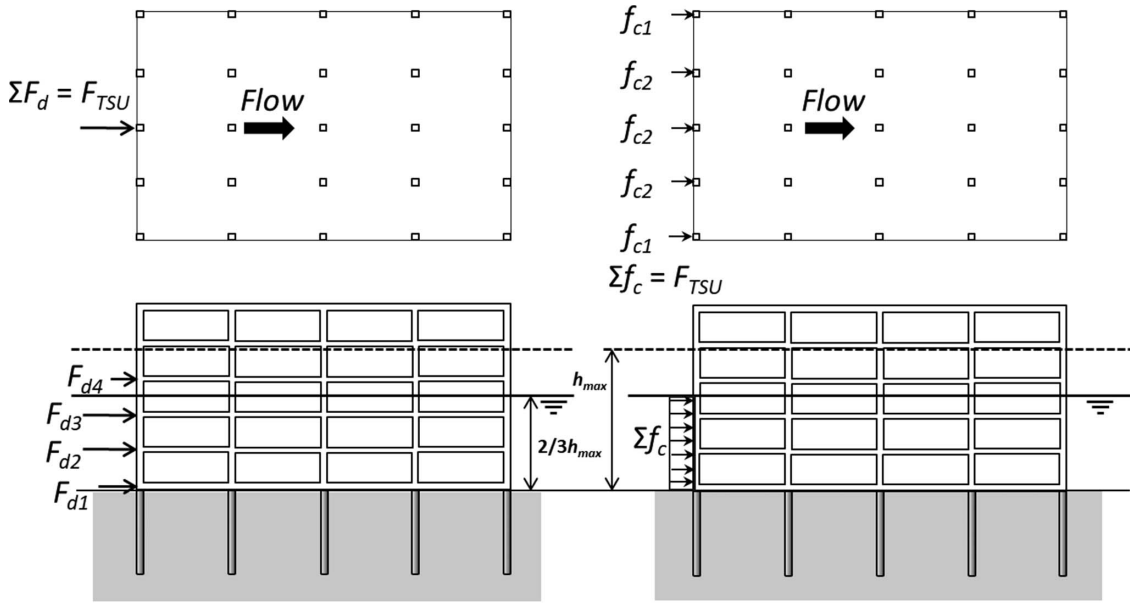
The capacity of minimum-code seismically designed Risk Category II structures using this technique was demonstrated in the Earthquake Engineering Research Institute (EERI) special issue of March 2013, in a paper providing analysis of prototypical buildings for tsunami and seismic requirements (Chock et al. 2013a). In this paper, several prototypical buildings were investigated, with the following assumptions.

Parameters for a comparison of overall systemic resistance to tsunami loading are as follows: (1) the prototypical Risk Category II buildings of increasing height selected for illustrative purposes were 120 ft (36.5 m) long and 90 ft (27.5 m) wide and are 25% open; (2) they were located in high seismic zones (in the United States, $S_s = 1.5$ and $S_1 = 0.6$); (3) connections developed the inelastic capacities of the members; (4) tsunami flow velocity was 26.2 ft/s (8 m/s); (5) each tsunami inundation load curve represented the continuum of hydrodynamic loading cases inundation increases to the maximum depth; and (6) seismic capacity is used based on the overstrength capacity. It was found by analysis that the structural systems of larger scaled and taller buildings are inherently less susceptible to tsunamis than this prototype, provided that there is adequate foundation anchorage for resistance to scour and uplift.

C6.8.3.5 Structural Component Acceptance Criteria The design of structural components shall comply with Section 6.8.3.5.1 or in accordance with the alternative performance-based criteria of Section 6.8.3.5.2 or 6.8.3.5.3, as applicable. The alternative Sections 6.8.3.5.2 and 6.8.3.5.3 are not prescriptive methods of analysis.

C6.8.3.5.1 Acceptability Criteria by Component Design Strength The primary means of determining structural component acceptability is based on a linear elastic analysis and the evaluation of resultant actions of the load combinations compared with the design strength of the structural components and connections.

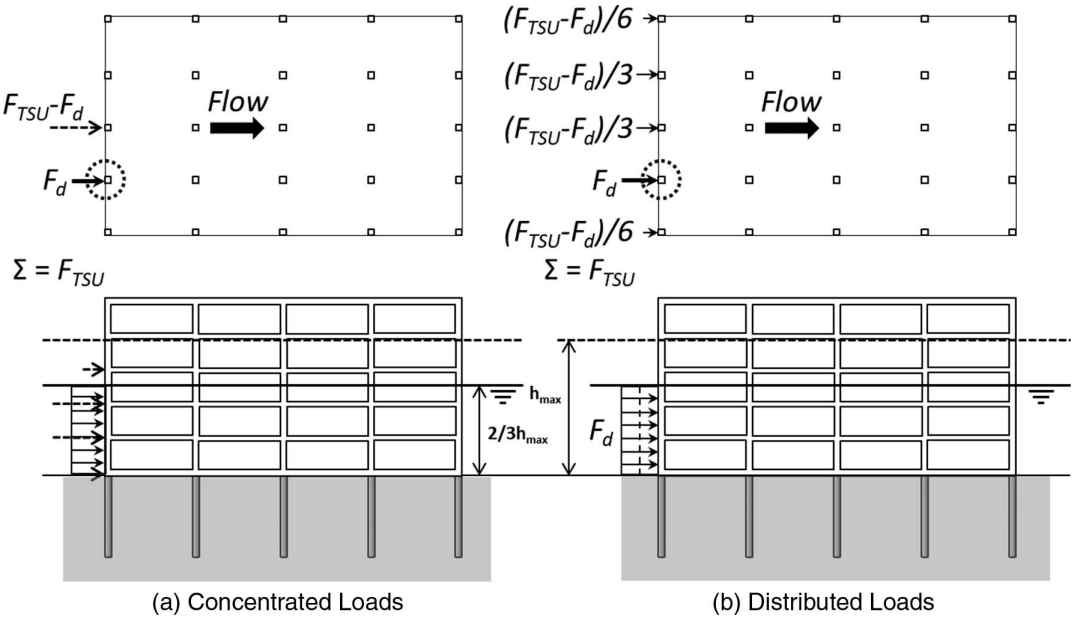
C6.8.3.5.2 Alternative Performance-Based Criteria The alternative structural component acceptability criteria use acceptance criteria of ASCE 41-17 (ASCE 2017b), *Seismic Evaluation and Retrofit of Existing Buildings*. With an adaptation of this method, strength and stability can be checked to determine that the design of the structural components is capable of withstanding the tsunami to achieve the Structural Performance level required. The tsunami adaption allows the techniques of linear static and nonlinear static analysis. For the purposes of this chapter, it may be appropriate to generically adapt modeling parameters nonspecific to earthquake ground motion from the nonlinear static procedure or simplified nonlinear static procedure of ASCE 41-17 (ASCE 2017b). For example, it should be acceptable to use the effective stiffness values of ASCE 41-17 (ASCE 2017b) for this purpose.



For the nonlinear static analysis procedure, the mathematical model of the structure is subjected to monotonically increasing loads until the required tsunami forces and applied actions are reached. The lateral-force-resisting system can be evaluated for the overall hydrodynamic drag force prescribed in Section 6.10.2.1 by simultaneously increasing both flow depth and flow velocity monotonically, in accordance with Figure 6.8-1, up to Load Case 2. When this procedure is used with a site-specific tsunami inundation analysis, the maximum load case is determined from the inundation depth and velocity time history results. These loads can be applied as concentrated loads at each floor level corresponding to the tributary height for that floor level (Figure C6.8-1a), or as distributed loads along the vertical load-bearing structural components (Figure C6.8-1b).

Individual structural components that are part of the lateral-force-resisting system must resist their portion of the overall drag force on the structure concurrently with the drag force on the individual component as specified in Sections 6.10.2.2 through 6.10.2.5. The drag force on the individual component is distributed uniformly along the length of the component and increased monotonically by simultaneously increasing both flow depth and flow velocity in accordance with Figure 6.8-1. The balance of the overall drag force on the structure is applied proportionally to the remainder of the lateral-force-resisting system. These loads can be applied as concentrated loads at each floor level corresponding to the tributary height for that floor level (Figure C6.8-2a), or as distributed loads along the vertical load-bearing structural components (Figure C6.8-2b). Application of this nonlinear static analysis procedure to a prototypical building and its structural components is demonstrated by Baiguera et al. (2020). The overall tsunami lateral drifts would generally induce some flexural and shear demands on individual components, even if they are not part of the lateral-force-resisting system.

Structural components can then be checked using the ASCE 41-17 acceptability criteria for actual tsunami loads and depths that are correct from the standpoint of fluid mechanics without load factors. Results of the analysis procedure shall not exceed the numerical acceptance criteria for linear procedures of ASCE 41-17 (Chapters 9 through 11) for the structural performance criteria required for the building or structure's tsunami risk category. For nonlinear static analysis procedures, expected deformation capacities shall be greater than or equal to the maximum deformation demands calculated at the required tsunami forces and applied actions.



C6.8.3.5.3 Alternative Acceptability by Progressive Collapse Avoidance. Where tsunami loads or effects exceed acceptability criteria for a structural element, a recognized method of checking the residual structural system gravity-load-carrying capacity is the alternate load path procedure given in *Design of Structures to Resist Progressive Collapse* (DOD 2013). An ASCE standard for progressive collapse avoidance is not yet available.

C6.8.4 Minimum Fluid Density for Tsunami Loads The tsunami inundation conditions relevant to structural design are by no means represented by pristine seawater. Overland flow is more similar to a debris flood, with suspended soil and debris objects of various sizes and materials. The fluid density factor, k_s, is used to account for such soil and debris within equivalent fluid forces that are not accounted for in Section 6.11, which deals with debris impacts by larger objects. The value of $k_s = 1.1$ was selected to represent an equivalent sediment concentration of 7%, assuming a specific gravity of 2.5 for the suspended soil particles.

C6.8.5 Flow Velocity Amplification Tsunami Design Zone Maps are based on so-called bare-earth conditions (i.e., without discrete objects) with an equivalent Manning's roughness to represent what exists above ground. When the Energy Grade Line Analysis is used with the Manning's roughness based on built environments, more energy is required to reach the specified mapped runup. Urban environments are expected to have a higher probability of generating flow amplification effects through numerous diffraction scenarios that are not possible to specifically enumerate. Nevertheless, the Energy Grade Line Analysis implemented with an urban area's roughness produces

@seismicisolation

sufficiently conservative depth and momentum flux, and additional flow amplification need not be considered. Therefore, to account for these possible effects, site flow velocities shall not be taken as less than 100% of those determined in accordance with the Energy Grade Line Analysis method of Section 6.6.

This section of the commentary provides some examples of flow diffraction effects taken from available North American research. Experimental studies discussed in Thomas et al. (2014) and Nouri et al. (2010) relate to flow amplification. The example of channelized flow conditions is inferred from the University of Ottawa experiments, and the results indicated for symmetrically arranged objects are based on Oregon State University experiments conducted in the Network for Earthquake Engineering Simulation (NEES) tsunami wave basin. Note that these tests were for higher Froude numbers than are used in the provisions. The explicit flow amplification cases described here are for places where the geometry of nearby structures leads to higher-than-normal flows.

Building types deemed unable to resist the tsunami hydrodynamic forces are to be excluded because they will not be able to redirect sustained flow to other buildings. Also, the provisions do not permit the shielding effect of neighboring structures to reduce flow velocity below the basic value derived from the Energy Grade Line Analysis method. The engineer should exercise judgment and conduct additional studies for other conditions where flow amplification would be expected based on the principles of fluid mechanics.

Flow Velocity Amplification for Channel Effect—University of Ottawa Research Discussed in Nouri et al. (2010). Where obstructing structures exist along each side of a street or open swath oriented parallel to the flow such that the ratio L/W is between 1 and 3 and W_c/W is between 0.6 and 0.8, as shown in Figure C6.8-3, the incident flow velocity amplification on a structure located at the end of such a channelized flow was found to be as shown in Figure C6.8-4, in which the blockage ratio is $1-W_c/W$.

Flow Amplification for Two Isolated Upstream Structures

This information is from Oregon State University Research discussed in Thomas et al. (2014). Where tsunami bores flow through a layout of two upstream isolated buildings in a

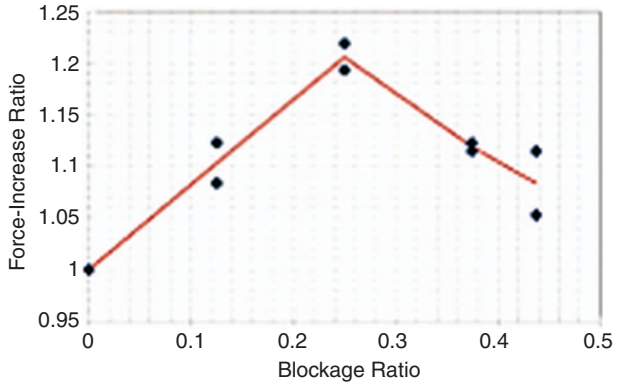

Figure C6.8-4. Flow amplification force-increase ratio for channelized conditions (where the blockage ratio is the net width of constricting obstructions divided by the total flume width).

symmetric arrangement, the net flow amplification factor downstream was found to be related to the effective wake clearance angle, β. The effective wake angle is shown in Figure C6.8-5, and a summary of results is shown in Figure C6.8-6 and Table C6.8-3. This figure also illustrates what is the center third of the width of the downstream structure.

The approximate envelope of the flow amplification factors is given in Table C6.8-3. Linear interpolation between the listed values is reasonable.

C6.8.5.2 Flow Velocity Amplification by Physical or Numerical Modeling The implementation of an alternative flow amplification analysis is expected to consist of a numerical model or an experimental model that is sufficiently documented to comply with Section 6.8.10. Park et al. (2013) provide a discussion of this approach.

C6.8.6 Directionality of Flow

C6.8.6.1 Flow Direction Rather than assume that the flow is uniformly perpendicular to the shoreline, variation by ±22.5 degrees from the perpendicular transect is considered, in which

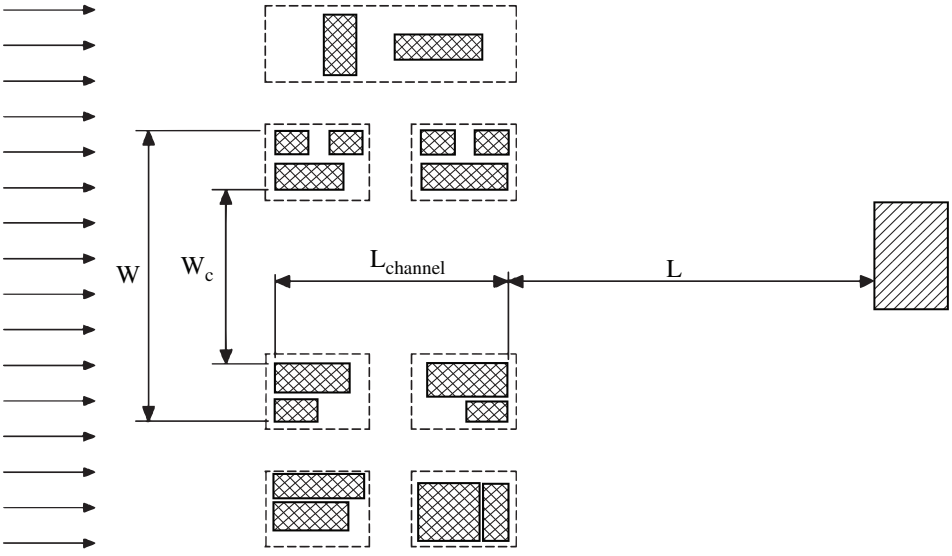

Figure C6.8-3. Flow amplification for channelized conditions.

@seismicisolation

the center of rotation of the possible transects is located at the site. The first objective is to find the highest runup elevation associated with the possible design transects. The second objective is to account for variation in the load application to the structure. The governing transect that produces the maximum runup elevation may be used to perform an Energy Grade Line Analysis, and the prescribed directional variation for the resulting flow parameters may be used to compute directional loads. Alternatively, an Energy Grade Line Analysis may be computed for each possible direction.

The determination of outflow direction may also require consideration that the outflow current may be affected by existing stream and riverbeds and drainage canals, as well as additional scour and sediment transport, which may cause significant morphological changes in topography during a vigorous draw-down cycle after a large watershed is inundated.

C6.8.6.2 Site-Specific Directionality Although a site-specific inundation analysis is permitted to establish flow vectoring at the site, some uncertainty in the accuracy of this estimation is reflected in the ±10-degree variability.

C6.8.7 Minimum Closure Ratio for Load Determination Loads on buildings shall be calculated assuming a minimum closure ratio of 70% of the pressure-exposed surface area of the exterior enclosure. This assumption accounts for accumulated waterborne debris trapped against the side of the structure, as well as any internal blockage caused by building contents that cannot easily flow out of the structure. As a practical matter based on observations of buildings subjected to destructive tsunami, "breakaway" walls cannot be totally relied on to relieve structural loading, primarily because of the copious amount of external debris. Also, studs and girts may be capable of entrapping contents within a building, thus generating hydrodynamic drag forces on the internal debris, which in turn transfers those loads to the structure (Chock et al. 2013a, b).

C6.8.8 Minimum Number of Tsunami Flow Cycles Designers working on loading shall consider a minimum of two tsunami inflow-and-outflow cycles, the second of which shall be at the Maximum Considered Tsunami design level. This consideration is required because the condition of the building and its foundation may change in each tsunami inflow and outflow cycle. Therefore,
